Abstract. In this chapter we review recent theoretical work on the statistical physics of error correcting codes. We discuss the typical performance of four families of error-correcting codes based on very sparse linear transformations: Sourlas codes, Gallager codes, MacKay-Neal codes and Cascading codes. By mapping the decoding problem onto Ising spin systems with multi-spins interactions we are able to calculate averages over code constructions, messages and noise. We find, as the noise level increases, a phase transition between successful decoding and failure phases. This phase transition coincides with upper bounds derived in the information theory literature in most cases. We relate the practical decoding algorithm known as probability propagation to the task of finding local minima of a free-energy. We show that practical decoding thresholds correspond to noise levels where suboptimal minima of the free-energy emerge. Simulation results of practical decoding scenarios using probability propagation agree with theoretical predictions of the statistical physics approach. The typical performance predicted by the phase transition picture is shown to be attainable only in computing times that grow exponentially with the message size. We use some of the physical insights obtained to design a method to calculate the performance and optimize parameters of cascading codes.

1. Introduction

1.1. Error-correction

The way we communicate has been deeply transformed during the twentieth century. Telegraph, telephone, radio and television technologies have brought to reality instantaneous long distance communication. Satellite and digital technologies have made global high-fidelity communication possible.

Two obvious common features of modern digital communication systems are that typically the message to be transmitted (e.g. images, text, computer programs) is redundant and the medium used for transmission (e.g. deep-space, atmosphere, optical fibres, etc...) is noisy. The key issues in modern communication are, therefore, saving storage space and computing time by eliminating redundancies (source coding or compression) and making transmissions reliable by employing error correction techniques (channel coding). Shannon was one of the first to point out these key issues. His influential 1948 papers [Sha48] proved general results on the natural limits of compression and error-correction by setting up the framework to what is now known as information theory.

Shannon’s channel coding theorem states that error-free communication is possible if some redundancy is added to the original message in the encoding process. A message encoded at rates \( R \) (message information content/code-word length) up to the channel capacity \( C_{\text{channel}} \) can be decoded with a probability of error that decays exponentially with the message length. Shannons proof was non-constructive and assumed encoding with unstructured random codes and impractical (non-polynomial time) [CT91] decoding schemes. Finding practical codes capable of reaching the natural coding limits is one of the central issues in coding theory.

To illustrate the difficulties that may arise when trying to construct high performance codes from first principles, we can use a simple geometric illustration. On the top left of Fig.1 we represent the space of words (a message is a sequence of words), each circle represents one sequence of binary bits. The word to be sent is represented by a black circle in the left side figure. Corruption by noise in the channel is represented in the top right figure as a drift in the original word location. The circle around each word represent spheres that provide a decision boundary for each particular word, any signal inside a certain decision region is recognized as representing the word at the center of the sphere. In the case depicted in Fig.1 the drift caused by noise places the received word within the decision boundary of another word vector, causing a transmission error. Error-correction codes are based on mapping the original space of words onto a higher dimensional space in a way that the typical distance between encoded words (codewords) increases. If the original space is transformed, the same drift shown in the top of Fig.1 is insufficient to push the received signal outside the decision boundary of the transmitted codeword (bottom figure).

Based on this simple picture we can formulate general designing criteria for good error-correcting codes: codewords must be short sequences of binary digits (for fast
transmission), the code must allow for a large number of codewords (for a large set of words) and decision spheres must be as large as possible (for large error-correction capability). The general coding problem consists of optimizing one of these conflicting requirements given the other two. So, for example, if the dimension of the lattice and diameter of decision spheres are fixed, the problem is finding the lattice geometry that allows the densest possible sphere packing. This sphere packing problem is included in the famous list of problems introduced by Hilbert (it is actually part of the 18th problem). This problem can be solved for a very limited number of dimensions [CS98], but is very difficult in general. As a consequence, constructive procedures are known only for a limited number of small codes.

For long, the best practical codes known were Reed-Solomon codes (RS), operating in conjunction with convolutional codes (concatenated codes). The current technological standard are RS codes, proposed in 1960, found almost everywhere from compact disks to mobile phones and digital television. Concatenated codes are the current standard in deep-space missions (e.g. Galileo mission) [MS77, OO79]. Recently, Turbo codes [BGT93] have been proven to outperform concatenated codes and are becoming increasingly more common. These codes are composed of two convolutional codes working in parallel and show practical performance close to Shannon’s bound when decoded with iterative methods known as probability propagation, first studied in the context of coding by Wiberg [Wib96].

Despite the success of concatenated and Turbo codes, the current performance
record is owned by Gallager's low-density parity-check codes, e.g., [Chu00, Dav99, Dav98]. Gallager codes were first proposed in 1962 [Gal62, Gal63] and then were all but forgotten soon after due to computational limitations of the time and due to the success of convolutional codes.

To give an idea of how parity-check codes operate, we exemplify with the simplest code of this type known as Hamming code [Ham50]. A (7, 4) Hamming code, where (7, 4) stands for the number of bits in the codeword and input message respectively, operates by adding 3 extra bits for each 4 message bits, this is done by a linear transformation \( G \), called the generator matrix, represented by:

\[
G = \begin{pmatrix}
1 & 0 & 0 & 0 \\
0 & 1 & 0 & 0 \\
0 & 0 & 1 & 0 \\
0 & 0 & 0 & 1 \\
0 & 1 & 1 & 1 \\
1 & 0 & 1 & 1 \\
1 & 1 & 0 & 1 \\
\end{pmatrix}.
\] (1)

When the generator matrix \( G \) is applied to a digital message \( s = (s_1, s_2, s_3, s_4) \), we get an encoded message defined by \( t = Gs \) composed of 4 message bits plus redundant information (parity-check) as 3 extra bits \( t_5 = s_2 \oplus s_3 \oplus s_4 \), \( t_6 = s_1 \oplus s_3 \oplus s_4 \) and \( t_7 = s_1 \oplus s_2 \oplus s_4 \) (\( \oplus \) indicates binary sums). One interesting point to note is that the transmitted message is such that \( t_5 \oplus s_2 \oplus s_3 \oplus s_4 = 0 \) and similarly for \( t_6 \) and \( t_7 \), what allows direct check of single corrupted bits. The decoding procedure relies in a second operator, known as parity-check matrix, with the property \( HG = 0 \). For the generator (1) the parity-check matrix has the following form:

\[
H = \begin{pmatrix}
0 & 0 & 0 & 1 & 1 & 1 & 1 \\
0 & 1 & 1 & 0 & 0 & 1 & 1 \\
1 & 0 & 1 & 0 & 1 & 0 & 1 \\
\end{pmatrix}.
\] (2)

The decoding procedure follows from the observation that the received message is corrupted by noise as \( r = Gs \oplus n \). By applying the parity-check matrix we get the syndrome \( Hr = Hn = z \). In the (7, 4) Hamming code the syndrome vector gives the binary representation for the position of the bit where an error has occurred (e.g. if \( n = (0, 0, 1, 0, 0, 0, 0) \), \( z = (0, 1, 1) \)). Due to this nice property decoding is trivial and this code is known as a perfect single-error-correcting code [Hil86].

Codes in the low-density parity-check family work along the same principles as the simple Hamming code above, the main differences are that they are much longer, the parity-check matrix is very sparse and multiple errors can be corrected. However, low-density parity-check codes are not perfect and the decoding problem is, in general, significantly more difficult. Luckily, the sparseness of the matrix allows for the decoding process to be carried out by probability propagation methods similar to those employed in Turbo codes. Throughout this chapter we concentrate on low-density parity-check codes (LDPC) that are state-of-the-art concerning performance and operate along simple
principles. We study four variations of LDPCs known as Sourlas codes, Gallager codes, MacKay-Neal codes and cascading codes.

1.2. Statistical physics of coding

The history of statistical physics application to error-correcting codes started in 1989 with a paper by Sourlas relating error-correcting codes to spin glass models [Sou89]. He showed that the Random Energy Model [Der81b, Saa98, DW99] can be thought of as an ideal code capable of saturating Shannon’s bound at vanishing code rates. He also showed that the SK model [KS78] could operate as a practical code.

In 1995, convolutional codes were analyzed by employing the transfer-matrix formalism and power series expansions [AL95].

In 1998, Sourlas work was extended for the case of finite code rates [KS99a, VSK99] by employing the replica method. Recently, Turbo codes were also analyzed using the replica method [MS00, Mon00].

In this chapter we present the extension of Sourlas work together with the analysis of other members in the family of low-density parity-check codes. We rely mainly on replica calculations [KMS00, MKSV00, VSK00b] and mean-field methods [KS98, VSK00a]. The main idea is to develop the application of statistical physics tools for analyzing error-correcting codes. A number of results obtained are rederivations of well known results in information theory, while others put known results into a new perspective.

The main differences between the statistical physics analysis and traditional results in coding theory are: the emphasis on very large systems from the start (thermodynamic limit) and the calculation of ensemble typical performances instead of worst case bounds. In this sense statistical physics techniques are complementary to traditional methods. As a byproduct of our analysis we connect the iterative decoding methods of probability propagation with well known mean-field techniques, presenting a framework that might allow a systematic improvement of decoding techniques.

1.3. Outline

In the next section we provide an overview of results and ideas from information theory that are relevant for understanding of the forthcoming sections. We also discuss more deeply linear encoding and parity-check decoding. We present the probability propagation algorithm for computing approximate marginal probabilities efficiently and finish by introducing the statistical physics point of view of the decoding problem.

In Section 3, we investigate the performance of error-correcting codes based on sparse generator matrices proposed by Sourlas. We employ replica methods to calculate the phase diagram for the system at finite code rates. We then discuss the decoding dynamics of the probability propagation algorithm. Sourlas codes are regarded as a first step towards developing techniques to analyze other more practical codes.

Section 4 provides a statistical physics analysis for Gallager codes. These codes use a dense generator and a sparse parity-check matrix. The code is mapped onto a K-body
interaction spin system and typical performance is obtained using the replica method. A mean-field solution is also provided by mapping the problem onto a Bethe-like lattice (Husimi cactus), recovering, in the thermodynamic limit, the replica symmetric results and providing a very good approximation for finite systems of moderate size. We show that the probability propagation decoding algorithm emerges naturally from the analysis and its performance can be predicted by studying the free-energy landscape. A simple technique is introduced to provide upper bounds for the practical performance.

In Section 5 we investigate MacKay-Neal codes that are a variation of Gallager codes. In these codes, decoding involves two very sparse parity-check matrices, one for the signal with K non-zero elements in each row and a second for the noise with L non-zero elements. We map MN codes onto a spin system with K + L interacting spins. The typical performance is again obtained by using a replica symmetric theory.

A statistical description for the typical PP decoding process for cascading codes is provided in Section 6. We use this description to optimize the construction parameters of a simple code of this type.

We close this chapter in Section 7 with concluding remarks. Appendices with technical details are also provided.

2. Coding and Statistical Physics

2.1. Mathematical model for a communication system

In his papers from 1948 [Sha48], Shannon introduced a mathematical model (schematically represented in Fig.2) incorporating the most basic components of communication systems, he identified key problems and proved some general results. In the following we will introduce the main components of Shannon’s communication model, the mathematical objects involved as well as related general theorems.
2.1.1. Data source and sink A data source can be discrete or continuous. A discrete source is defined by the pair \((\mathcal{S}, \pi)\), where \(\mathcal{S}\) is a set of \(m\) symbols (alphabet) and \(\pi\) is a probability measure over the space of sequences of symbols with any length (messages). In general any discrete alphabet can be mapped onto sequences of \([\log m]\) Boolean digits \(\{0, 1\}\). Continuous sources can always be made discrete at the expense of introducing some distortion to the signal [CT91]. A source is memoryless if each symbol in the sequence is independent of the preceding and succeeding symbols. A data sink is simply the receiver of decoded messages.

2.1.2. Source encoder and decoder Data sources usually generate redundant messages that can be compressed to vectors of shorter average length. Source encoding, also known as data compression, is the process of mapping sequences of symbols from an alphabet \(\mathcal{S}\) onto a shorter representation \(\mathcal{A}\).

Shannon employed the statistical physics idea of entroy to measure the essential information content of a message. As enunciated by Khinchin [Khi57], the entropy of Shannon is defined as follows:

**Definition 1 (Entropy)** Let

\[
\begin{pmatrix}
  a_1 & a_2 & \cdots & a_m \\
  p_1 & p_2 & \cdots & p_m
\end{pmatrix}
\]

be a finite scheme, where \(a_j\) are mutually exclusive events and \(p_j\) are associated probabilities with \(\sum_{j=1}^{m} p_j = 1\). The entropy of the scheme in bits (or shannons) is defined as

\[
H_2(A) = -\sum_{j=1}^{m} p_j \log_2 p_j.
\]  

The entropy is usually interpreted as the amount of information gained by removing the uncertainty and determining which event actually occurs.

Shannon [Sha48] posed and proved a theorem that establishes the maximal shortening of a message by compression as a function of its entropy. The compression coefficient can be defined as \(\mu \equiv \lim_{N \to \infty} \langle L_N \rangle / N\), where \(N\) is the original message length and \(\langle L_N \rangle\) is the average length of compressed messages. As presented by Khinchin [Khi57] the theorem states:

**Theorem 1 (Source compression)** Given a discrete source with \(m\) symbols and entropy of \(H\) bits, for any possible compression code, the compression coefficient is such that

\[
\frac{H}{\log_2 m} \leq \mu
\]

and there exists a code such that

\[
\mu < \frac{H + \epsilon}{\log_2 m}
\]

for arbitrarily small \(\epsilon\).
A compression scheme that yields a coefficient $\mu$ within the bounds above, given that the statistical structure $\pi$ of the source is known, was proposed in 1952 by Huffman [Huf52]. Several practical algorithms are currently known and the design of more efficient and robust schemes is still a very active research area [NG95].

2.1.3. Noisy channels Message corruption during transmission can be described by a probabilistic model defined by the conditional probability $P(r \mid t)$ where $t$ and $r$ represent transmitted and received messages respectively. We can assume that in any of the channels used, only one component $t_j$, $j = 1, \ldots, M$ of the original message is being sent. If there is no interference effects between components, the channel is memoryless and the conditional probability factorizes as $P(r \mid t) = \prod_{j=1}^{M} P(r_j \mid t_j)$.

A memoryless channel model is specified by $(T, P(r \mid t), \mathcal{R})$, where $T$ and $\mathcal{R}$ are input and output alphabets and $P(r \mid t)$ transition probabilities. The information needed to specify $t$ given the received signal $r$ is the conditional entropy:

$$H_2(T \mid R) = -\sum_{r \in \mathcal{R}} P(r) \left[ \sum_{t \in T} P(t \mid r) \log_2 (P(t \mid r)) \right].$$

The information on the original signal $t$ conveyed by the received signal $r$ is given by the mutual information $I(T; R) = H_2(T) - H_2(T \mid R)$, where $H_2(T)$ is defined in (3). The maximal information per bit that the channel can transport defines the channel capacity [CT91].

Definition 2 (Channel capacity) Given the channel model, the channel capacity is

$$C_{\text{channel}} = \max_{P(t)} I(T; R),$$

where $I(T; R)$ is understood as a functional of the transmitted bits distribution $P(t)$. Thus, for example, if $C_{\text{channel}} = 1/2$, in the best case, 2 bits must be transmitted for each bit sent.

The following channel model (see [Mac99, Mac00a]) is of particular interest in this chapter:

Definition 3 (Binary symmetric channel) The memoryless binary symmetric channel (BSC) is defined by binary input and output alphabets $T = \mathcal{R} = \{0, 1\}$ and by the conditional probability

$$P(r \neq t \mid t) = p \quad P(r = t \mid t) = 1 - p.$$  \hspace{1cm} (5)

The channel capacity of a BSC is given by

$$C_{BSC} = 1 - H_2(p) = 1 + p \log_2 (p) + (1 - p) \log_2 (1 - p).$$

In the current chapter we concentrate on the binary symmetric channel due to its simplicity and straightforward mapping onto an Ising spin system. However, there are several other channel types that have been examined in the literature, and that play an important role in practical applications [O0T9, CT91]. The most important of these is arguably the Gaussian channel; most of the analysis presented in this chapter can be carried out in the case of the Gaussian channel as demonstrated in [KS99a, VSK99].
2.1.4. Channel encoder and decoder. Highly reliable communication is possible even through noisy channels. It can be achieved by protecting a message with redundant information using a channel encoder defined as:

**Definition 4 ((\(2^N, M\) Code)** A code of rate \( R = N/M \) is an indexed list (codebook) of \( 2^N \) codewords \( t(i) \in \mathcal{T} \) each of length \( M \). Each index \( i \) in the codebook corresponds to a possible sequence of message bits.

In a digital system, a code can be regarded as a map of representations of \( 2^N \) symbols as Boolean sequences of \( N \) bits onto Boolean sequences of \( M \) bits. In Fig.3 we show the codebook for the Hamming code defined by (1) that is a \((2^4, 7)\) code. Each sequence of \( N = 4 \) message bits is indexed and converted in a codeword with \( M = 7 \) bits.

A decoding function \( g \) is a map of a channel output \( r \in \mathcal{R} \) back into a codeword. The probability that a symbol \( i \) is decoded incorrectly is given by the **probability of block error**:

\[
p_{\text{Block}} = P\{g(r) \neq i \mid t = t(i)\}. \tag{6}\]

The average probability that a decoded bit \( \hat{s}_j = g_j(r) \) fails to reproduce the original message bits is the **probability of bit error**:

\[
p_b = \frac{1}{N} \sum_{j=1}^{N} P\{\hat{s}_j \neq s_j\}. \tag{7}\]

Shannon’s coding theorem is as follows [CT91, Mac00a]:

**Theorem 2 (Channel coding)** The affirmative part of the theorem states:

For every rate \( R < C_{\text{channel}} \), there exists a sequence of \((2^{MR}, M)\) codes with maximum probability of block error \( p_{\text{Block}}^{(M)} \rightarrow 0 \). Conversely, any sequence of \((2^{MR}, M)\) codes with \( p_{\text{Block}}^{(M)} \rightarrow 0 \) must have \( R \leq C_{\text{channel}} \).

The negative part of the theorem is a corollary of the affirmative part and states:

Error free communication above the capacity \( C_{\text{channel}} \) is impossible. It is not possible to achieve a rate \( R \) with probability of bit error smaller than

\[
p_b(R) = H_2^{-1} \left( 1 - \frac{C_{\text{channel}}}{R} \right). \tag{8}\]
This non-constructive theorem is obtained by assuming ensembles of random codes and impractical decoding schemes. No practical coding scheme (i.e. that can be encoded and decoded in polynomial time) that saturates the channel capacity is known to date. As Shannon’s proof does not deal with complexity issues, there is no guarantee that such practical scheme exists at all.

2.2. Linear error-correcting codes and the decoding problem

Linear error-correction codes add redundancy to the original message \( s \in \{0, 1\}^N \) through a linear map like:

\[
t = G s \quad \text{(mod 2)},
\]

where \( G \) is an \( M \times N \) Boolean matrix. The received message \( r = t + n \) is a corrupted version of the transmitted message. In the simplest form, optimal decoding consists of finding an optimal estimate \( \hat{s}(r) \) assuming a model for the noisy channel \( P(r \mid t) \) and a prior distribution for the message source \( P(s) \).

The definition of the optimal estimator depends on the particular task and loss function assumed. An optimal estimator is defined as follows (see [Iba99] and references therein):

**Definition 5 (Optimal estimator)** An optimal estimator \( \hat{s}(r) \) for a loss function \( L(s, \hat{s}(r)) \) minimizes the average of \( L \) in relation to the posterior distribution \( P(s \mid r) \).

A posterior probability of messages given the corrupted message received can be easily found by applying Bayes theorem:

\[
P(s \mid r) = \frac{P(r \mid t) \delta(t; Gs) P(s)}{\sum_s P(r \mid t) \delta(t; Gs) P(s)},
\]

where \( \delta(x; y) = 1 \) if \( x = y \) and \( \delta(x; y) = 0 \), otherwise.

If we define our task to be the decoding of perfectly correct messages (i.e. we are interested in minimizing the probability of block error \( p_{\text{Block}} \), we have to employ a two-valued loss function that identifies single mismatches:

\[
L(s, \hat{s}(r)) = 1 - \prod_{j=1}^{M} \delta(s_j; \hat{s}_j).
\]

An optimal estimator for this loss function must minimize the following:

\[
\langle L(s, \hat{s}(r)) \rangle_{P(s \mid r)} = \sum_s P(s \mid r) L(s, \hat{s}(r))
\]

\[
= 1 - \sum_s P(s \mid r) \prod_{j=1}^{M} \delta(s_j; \hat{s}_j)
\]

\[
= 1 - P(\hat{s} \mid r).
\]

Clearly, the optimal estimator in this case is \( \hat{s} = \arg \max_s P(s \mid r) \). This estimator is often called the *Maximum a Posteriori estimator* or simply *MAP*. 

If we tolerate a certain degree of error in the decoded message (i.e. we are instead interested in minimizing the probability of bit error \( p_b \)), the loss function has to be an error counter like:

\[
L(s, \hat{s}(r)) = - \sum_{j=1}^{M} s_j \hat{s}_j,
\]

where we assume for simplicity the binary alphabet \( s \in \{ \pm 1 \}^N \). The optimal estimator must minimize the following:

\[
\langle L(s, \hat{s}(r)) \rangle_{P(s|r)} = - \sum_{j=1}^{M} \langle s_j \rangle_{P(s|r)} \hat{s}_j.
\]

An obvious choice for the estimator is

\[
\hat{s}_j = \frac{\langle s_j \rangle_{P(s|r)}}{\sum_{k \neq j} \langle s_k \rangle_{P(s|r)}} = \text{sign} \left( \langle s_j \rangle_{P(s|r)} \right) = \arg \max_{s_j} P(s_j | r),
\]

where \( P(s_j | r) = \sum_{s_k : k \neq j} P(s | r) \) is the marginal posterior distribution. As suggested by Eq. (15), this estimator is often called the Marginal Posterior Maximizer or MPM for short.

Decoding, namely, the computation of estimators, becomes a hard task, in general, as the message size increases. The MAP estimator requires finding a global maximum of the posterior over a space with \( 2^N \) points and the MPM estimator requires to compute long summations of \( 2^{N-1} \) terms for finding the two valued marginal posterior. The exponential scaling makes a naïve brute force evaluation quickly impractical, at least in . An alternative is to use approximate methods to evaluate posteriors, popular methods are Monte-Carlo sampling and the computationally more efficient probability propagation. In the sequence we will discuss the latter.

2.3. Probability propagation algorithm

The probabilistic dependencies existing in a code can be represented as a bipartite graph [Lau96] where nodes in one layer correspond to the \( M \) received bits \( r_k \) and nodes in the other layer to the \( N \) message bits \( s_j \). The connections between the two layers are specified by the generator matrix \( G \). Decoding requires evaluation of posterior probabilities when the received bits \( r \) are known (evidence).

The evaluation of the MPM estimator requires the computation of the following marginal joint distribution:

\[
P(s_j, r) = \sum_{\{s_i : i \neq j\}} P(s | r)P(r)
\]

\[
= \sum_{\{s_i : i \neq j\}} P(r | s)P(s)
\]
Figure 4. Bayesian network representing a linear code of rate 2/3. If there is an arrow from a vertex $s_j$ to a vertex $r_\mu$, $s_j$ is said to be a parent and $r_\mu$ is said to be a child.

\[
= \sum_{\{s_i : i \neq j\}} \prod_{\mu=1}^{M} P(r_\mu \mid s_i \cdots s_k) \prod_{j=1}^{N} P(s_j),
\]

where $s_i \cdots s_k$ are message bits composing the transmitted bit $t_\mu = (Gs)_\mu = s_i \oplus \cdots \oplus s_k$ and $r$ is the message received. Equation (16) shows a complex partial factorization that depends on the structure of the generator matrix $G$. We can encode this complex partial factorization on a directed graph known as a Bayesian network [Pea88, CGH97, Jen96, KF98, AM00, Fre98, KFL01]. As an example, we show in Fig.4 a simple directed bipartite graph encoding the following joint distribution:

\[
P(s_1, \cdots, s_4, r_1, \cdots, r_6) = P(r_1 \mid s_1, s_2, s_3)P(r_2 \mid s_3)P(r_3 \mid s_1, s_2)
\]

\[
\times P(r_4 \mid s_3, s_4)P(r_5 \mid s_5)P(r_6 \mid s_3)
\]

\[
\times P(s_1)P(s_2)P(s_3)P(s_4)
\]

The generator matrix for the code in Fig.4 is:

\[
G = \begin{pmatrix}
1 & 1 & 1 & 0 \\
0 & 1 & 0 & 0 \\
1 & 1 & 0 & 0 \\
0 & 0 & 1 & 1 \\
0 & 0 & 1 & 0 \\
0 & 0 & 1 & 0
\end{pmatrix}.
\]

Given $r$, an exact evaluation of the marginal joint distribution (16) in a space of binary variables $s \in \{\pm 1\}^N$ would require $(N + M)(2^{N-1} - 1) + 1$ operations. In the eighties Pearl [Pea88] proposed an iterative algorithm that requires $O(N)$ computational steps to calculate approximate marginal probabilities using Bayesian networks. This algorithm is known as belief propagation [Pea88], probability propagation [KF98], generalized distributive law [AM00] or sum-product algorithm [Fre98, KFL01] (see also [OS01]).

The probability propagation algorithm is exact when the Bayesian network associated to the particular problem is free of loops. To introduce the probability
propagation algorithm we start with the simple chain in Fig. 5, which represents the following joint distribution:

\[
p(s_1, s_2, s_3, s_4, s_5) = p(s_1)p(s_2 | s_1)p(s_3 | s_2)p(s_4 | s_3)p(s_5 | s_4). \tag{19}
\]

Suppose now that we would like to compute \( p(s_3) \), we would then have to compute:

\[
p(s_3) = \sum_{s_1, s_2, s_4, s_5} p(s_1)p(s_2 | s_1)p(s_3 | s_2)p(s_4 | s_3)p(s_5 | s_4). \tag{20}
\]

A brute force evaluation of (20) would take \( 5 \times (2^4 - 1) + 1 = 61 \) operations in a binary field. The probability propagation algorithm reduces significantly the number of operations needed by rationalizing the order in which they are performed. For Fig 5 we can start by marginalizing vertex \( s_5 \) and writing:

\[
R_{54}(s_4) = \sum_{s_5} p(s_5 | s_4). \tag{21}
\]

The function \( R_{54}(s_4) \) can be regarded as a vector (a message) carrying information about vertex \( s_5 \). In a similar way we can write:

\[
R_{43}(s_3) = \sum_{s_4} p(s_4 | s_3)R_{54}(s_4). \tag{22}
\]

Again \( R_{43}(s_3) \) can be seen as a message carrying information about vertices \( s_4 \) and \( s_5 \). Note that we can write (21) in the same form as (22) by assuming that \( R_5(s_5) = 1 \) if \( s_5 \) is not given or \( R_5(s_5) = \delta(s_5; s^*) \) if \( s_5 = s^* \), where \( \delta(x; y) = 1 \) if \( x = y \) and \( \delta(x; y) = 0 \), otherwise.

We can also gather information from vertices to the left of \( s_3 \). Firstly, we marginalize \( s_1 \) by introducing:

\[
Q_{12}(s_1) = p(s_1). \tag{23}
\]

We then propagate the message \( Q_{12}(s_1) \) to \( s_2 \) producing a new message:

\[
Q_{23}(s_2) = \sum_{s_1} Q_{12}(s_1)p(s_2 | s_1). \tag{24}
\]
The marginal probability \( p(s_3) \) can be finally computed by:

\[
p(s_3) = \sum_{s_2} Q_{23}(s_2)R_{43}(s_3)p(s_3 | s_2)
\]

\[
= \sum_{s_2} \sum_{s_1} Q_{12}(s_1)p(s_2 | s_1) \sum_{s_4} p(s_4 | s_3)R_{54}(s_4)p(s_3 | s_2)
\]

\[
= \sum_{s_2} \sum_{s_1} p(s_1)p(s_2 | s_1) \sum_{s_4} p(s_4 | s_3) \sum_{s_5} p(s_5 | s_4)
\]

\[
= \sum_{s_1,s_2,s_4,s_5} p(s_1)p(s_2 | s_1)p(s_3 | s_2)p(s_4 | s_3)p(s_5 | s_4). \tag{25}
\]

The evaluation of \( p(s_3) \) using probability propagation is exact and requires only 16 operations, much less than the 61 operations required for the brute force calculation.

A slightly more complex situation is shown in Fig. 6 representing the following joint distribution:

\[
p(s_1, ..., s_{12}) = p(s_6)p(s_8)p(s_9)p(s_{10})p(s_{11})p(s_{12})p(s_1 | s_{10})p(s_2 | s_{11}, s_{12})
\]

\[
\times p(s_3 | s_1, s_2, s_9)p(s_4 | s_3, s_8)p(s_5 | s_3, s_6)p(s_7 | s_4). \tag{26}
\]

Suppose that the variables are binary, \( s_7 \) and \( s_5 \) are given evidence vertices and we would like to compute the marginal \( p(s_3) \). A brute force evaluation would require \( 11 \times (2^9 - 1) + 1 = 5622 \) operations.

In general we can just initialize the messages with random values, or make use of prior knowledge that may be available, and update the vertices in a random order, but this may require several iterations for convergence to the correct values. In the particular case of trees there is an obvious optimal scheduling that takes only one iteration per vertex to converge: start at the leaves (vertices with a single edge connected to them) and proceed to the next internal level until the intended vertex. For the tree in Fig.6 the optimal schedule would be as follows:

- \( Q_{11,2}, Q_{12,2}, Q_{10,1}, Q_{65}, Q_{33}, Q_{84} \) and \( R_{74} \)
- \( Q_{13}, Q_{23} \) and \( R_{43}, R_{53} \)

The Q-messages are just the prior probabilities:

\[
Q_{j\theta}(s_j) = p(s_j), \tag{27}
\]

where \( j = 6, 8, 9, 10, 11, 12 \).

The R-message between \( s_7 \) and \( s_4 \) is:

\[
R_{74}(s_4) = \sum_{s_7} R_7(s_7)p(s_7 | s_4), \tag{28}
\]

where \( R_7(s_7) = \delta(s_7, s_7^e) \) and \( s_7^e \) is the value fixed by the evidence.

Following the schedule we have the following Q-messages:

\[
Q_{13}(s_1) = \sum_{s_{10}} p(s_1 | s_{10})Q_{10,1}(s_{10}) \tag{29}
\]

\[
Q_{23}(s_2) = \sum_{s_{11,s_{12}}} p(s_2 | s_{11,s_{12}})Q_{11,2}(s_{11})Q_{12,2}(s_{12}). \tag{30}
\]
The remaining R-messages are:

\[
R_{43}(s_3) = \sum_{s_4, s_8} p(s_4 \mid s_3, s_8)Q_{84}(s_8)R_{74}(s_4) \quad \text{(31)}
\]

\[
R_{53}(s_3) = \sum_{s_5, s_5} p(s_5 \mid s_3, s_6)Q_{65}(s_6)R_5(s_5), \quad \text{(32)}
\]

where \( R_5(s_5) = \delta(s_5, s_5^*) \) and \( s_5^* \) is the value fixed by the evidence.

Finally we can fuse all the messages in the vertex \( s_3 \) as follows:

\[
p(s_3) = \sum_{s_1, s_2, s_9} p(s_3 \mid s_1, s_2, s_9)Q_{13}(s_1)Q_{23}(s_2)R_{43}(s_3)R_{53}(s_3)Q_{93}(s_9). \quad \text{(33)}
\]

By substituting the expressions for the messages in (33) it is relatively straightforward to verify that this expression gives the exact value for the marginal of (26). In this case the probability propagation algorithm requires only 432 operations against 5622 operations required by the brute force evaluation.
We can now summarize the rules for calculating the message that flows through a particular edge:

- Multiply all incoming messages by the local probability table (for example: \( p(s_3 \mid s_1, s_2, s_3) \) for vertex \( s_3 \)) and sum over all vertices not attached to the edge that carries the outgoing message.
- Both Q and R messages must be only functions of the parent in the edge through which the message is flowing.

Probability propagation is only exact if the Bayesian network associated has no cycles. However, we can blindly apply the same algorithm in a general graph hoping that convergence to a good approximation is attained. In this kind of application there is no obvious optimal schedule and nodes can be updated serially, in parallel or randomly.

Before writing the probability propagation equations for a general graph let us first provide some definitions. Two vertices \( s_j \) and \( r_\mu \) are adjacent if there is an edge connecting them. If there is an arrow from \( s_j \) to \( r_\mu \), \( s_j \) is said to be a parent and \( r_\mu \) a child. The children of \( s_j \) are denoted by \( \mathcal{M}(j) \) and the parents of \( r_\mu \) are \( \mathcal{L}(\mu) \). Linear codes are specified by bipartite graphs (like in Fig.4) where all parents are in one layer and all children in the other layer. A message is a probability vector \( Q = (Q^0, Q^1) \) with \( Q^0 + Q^1 = 1 \). The probability propagation algorithm in a bipartite graph operates by passing messages between the two layers through the connection edges, first forwards from the top layer (parents) to the bottom layer (children), then backwards, and so on iteratively. Child-to-parent messages (backward messages in Fig.4) are \( R \)-messages denoted \( R_{\mu,j} \), while parent-to-child messages (forward messages) are \( Q \)-messages denoted by \( Q_{j\mu} \).

With the help of Fig.7 using the algorithm above the forward (\( Q \)) messages between a parent \( s_j \) and child \( r_\mu \) are just (see also [Dav99]):

\[
Q_{j\mu}^a = P(S_j = a \mid \{J_\nu : \nu \in \mathcal{M}(j) \setminus \mu \}) \\
= \alpha_{j\mu} p(s_j = a) \prod_{\nu \in \mathcal{M}(j) \setminus \mu} R_{\nu,j}^a,
\]

(34)

where \( \alpha_{j\mu} \) is a required normalization, \( \mathcal{M}(j) \setminus \mu \) stands for all elements in the set \( \mathcal{M}(j) \) except \( \mu \).

Similarly we can get the expression for the backward (\( R \)) messages between child \( r_\mu \) and parent \( s_j \):

\[
R_{\mu,j}^a = \sum_{\{s_i : i \in \mathcal{L}(\mu) \setminus j \}} P(r_\mu = a, \{s_i : i \in \mathcal{L}(\mu) \setminus j \}) \prod_{i \in \mathcal{L}(\mu) \setminus j} Q_{i\mu}^a.
\]

(36)

An approximation for the marginal posterior can be obtained by iterating Equations (34) and (36) until convergence or some stopping criteria is attained, and fusing all incoming information to a parent node by calculating:

\[
Q_j^a = \alpha_j p(s_j = a) \prod_{\nu \in \mathcal{M}(j)} R_{\nu,j}^a,
\]

(37)
where $\alpha_j$ is a normalization $Q^*_j$ is an approximation for the marginal posterior $P(s_j \mid r)$. Initial conditions can be set to the prior probabilities $Q^*_j = p(s)$.

It is clear (see also [Pea88]) that the probability propagation (PP) algorithm is exact if the associated graph is a tree and that the convergence for the exact marginal posterior occurs within a number of iterations proportional to the diameter of the tree. However, graphs defining error-correcting codes always have cycles and it has been observed empirically that decoding with the PP algorithm also yields good results [FM98, Che97] in spite of that.

There are a number of studies of probability propagation in loopy graphs with a single cycle [Wei97] and describing Gaussian joint distributions [Fre99] but no definite explanation for its good performance in this case is known to date.

2.4. Low-density parity check codes

Marginal posteriors can be calculated in $O(NK)$ steps, where $K$ is the average connectivity of a child node, by using probability propagation. Therefore, the use of very sparse generator matrices ($\sum_{n_j} G_{nj} = O(N)$) seems favorable. Moreover, it is possible to prove that the probability of a cycle-free path of length $l$ in a random graph decays with $O(K^l/N)$, that indicates that small cycles are harder to find if the generator matrix is very sparse and that PP decoding is expected to provide better approximations for the marginal posterior (no proof is known for this statement). Encoding is also faster if very sparse matrices are used, requiring $O(N)$ operations. Despite the advantages, the use of very sparse matrices for encoding has the serious drawback of producing codewords that differ in only $O(K)$ bits from each other, what leads to a high probability of undetectable errors. Codes with sparse generator matrices are known as Sourlas codes and will be our object of study in the next Section.

A solution for the bad distance properties of sparse generator codes is to use a dense matrix for encoding (providing a minimum distance between codewords of $O(N)$), while decoding is carried out in a very sparse graph, allowing efficient use of PP decoding. The method known as parity-check decoding [Hil86, 0079] is suitable in this situation, as encoding is performed by a generator matrix $G$, while decoding is done by transforming the corrupted received vector $r = Gs + n$ (mod 2) with a suitable parity check matrix $H$ having the property $HG$ (mod 2) = 0, yielding the syndrome vector $z = Hn$ (mod 2).

Decoding reduces to finding the most probable vector $n$ when the syndrome vector $z$ is known, namely, MPM estimates involve the calculation of the marginal posterior $P(n_j \mid z)$. In [Mac99], MacKay proved that this decoding method can attain vanishing block error probabilities up to the channel capacity if optimally decoded (not necessarily practically decoded).

This type of decoding is the basis for the three families of codes (Gallager, MacKay-Neal and cascading we study in this chapter.
2.5. Decoding and statistical physics

The connection between spin systems in statistical physics and digital error correcting codes, first noted by Sourlas [Sou89], is based on the existence of a simple isomorphism between the additive Boolean group \((\{0, 1\}, \oplus)\) and the multiplicative binary group \((\{+1, -1\}, \cdot)\) defined by:

\[
S \cdot X = (-1)^s \odot x,
\]  
(38)

where \(S, X \in \{+1, -1\}\) and \(s, x \in \{0, 1\}\). Through this isomorphism every addition on the Boolean group corresponds to a unique product on the binary group and vice versa. A parity-check bit in a linear code is usually formed by a Boolean sum of \(K\) bits of the form \(\bigoplus_{j=1}^{K} s_j\) what can be mapped onto a \(K\)-spin coupling \(\prod_{j=1}^{K} S_j\). The same type of mapping can be applied to other error-correcting codes as convolutional codes [Sou94b, AL95] and Turbo codes [MS00, Mon00].

The decoding problem depends on posteriors like \(P(S \mid J)\), where \(J\) is the evidence (received message or syndrome vector). By applying Bayes’ theorem this posterior can, in general, be written in the form:

\[
P_{\alpha, \gamma}(S \mid J) = \frac{1}{Z(J)} \exp \left[ \ln P_{\alpha}(J \mid S) + \ln P_{\gamma}(S) \right],
\]  
(39)

where \(\alpha\) and \(\gamma\) are hyper-parameters assumed to describe features like the encoding scheme, source distribution and noise level. This form suggests the following family of Gibbs measures:

\[
P_{\alpha, \beta, \gamma}(S \mid J) = \frac{1}{Z} \exp \left[ -\beta H_{\alpha, \gamma}(S; J) \right]
\]  
(40)

\[
H_{\alpha, \gamma}(S; J) = -\ln P_{\alpha}(J \mid S) - \ln P_{\gamma}(S),
\]  
(41)

where \(J\) can be regarded as quenched disorder in the system. It is not difficult to see that the MAP estimator is represented by the ground state of the Hamiltonian (40), i.e. by the sign of thermal averages \(\bar{S}_{j}^{\text{MAP}} = \text{sgn}(\langle S_j \rangle)_{\beta \to \infty}\) at zero temperature. On the other hand the MPM estimator is provided by the sign of thermal averages \(\bar{S}_{j}^{\text{MPM}} = \text{sgn}(\langle S_j \rangle)_{\beta=1}\) at temperature one. We have seen in that if we are concerned with the probability of bit error \(p_e\) the optimal choice for an estimator is MPM, this is equivalent to decoding at finite temperature \(\beta = 1\), known as the Nishimori temperature [Nis80, Nis93, Nis01, Ruj93].

The evaluation of typical quantities involves the calculation of averages over the quenched disorder (evidence) \(J\), namely, averages over:

\[
P_{\alpha^*, \gamma^*}(J) = \sum_S P_{\alpha^*}(J \mid S) P_{\gamma^*}(S),
\]  
(42)

where \(\alpha^*\) and \(\gamma^*\) represent the “real” hyper-parameters, in other words, the hyper-parameters actually used for generating the evidence \(J\). Those “real” hyper-parameters are, in general, not known to the receiver, but can be estimated from the data. To calculate these estimates we can start by writing free-energy like negative log-likelihoods for the hyper-parameters:

\[
\langle F(\alpha, \gamma) \rangle_{P_{\alpha, \gamma}} = -\langle \ln P_{\alpha, \gamma}(J) \rangle_{P_{\alpha, \gamma}}.
\]  
(43)
This log-likelihood can be regarded as measuring the typical plausibility of \( \alpha \) and \( \gamma \), given the data \( \mathbf{J} \) [Ber93]. This function can be minimized to find the most plausible hyper-parameters (known as type II maximum likelihood hyper-parameters or just ML-II hyper-parameters) [Ber93].

The ML-II hyper-parameters correspond in this case to \( \alpha = \alpha^* \) and \( \gamma = \gamma^* \), i.e. the “real” hyper-parameters must be used in the posterior for decoding. This fact is a consequence of the following inequality:

\[
\langle F(\alpha^*, \gamma^*) \rangle_{P_{\alpha^*, \gamma^*}} \leq \langle F(\alpha, \gamma) \rangle_{P_{\alpha, \gamma^*}}.
\]  

(44)

The proof of (44) follows directly from the information inequality [Iba99, CT91], i.e. the non-negativity of the KL-divergence:

\[
D(P_{\alpha^*, \gamma^*} \| P_{\alpha^*, \gamma}) \geq 0
\]

\[
\left\langle \ln \left( \frac{P_{\alpha^*, \gamma^*}(\mathbf{J})}{P_{\alpha^*}(\mathbf{J})} \right) \right\rangle_{P_{\alpha^*, \gamma^*}} \geq 0
\]

\[
-\langle \ln P_{\alpha^*, \gamma^*}(\mathbf{J}) \rangle_{P_{\alpha^*, \gamma^*}} \leq -\langle \ln P_{\alpha^*}(\mathbf{J}) \rangle_{P_{\alpha^*, \gamma^*}}.
\]  

(45)

When the true and assumed hyper-parameters agree, we say that we are at the Nishimori condition [Iba99, Nis01]. At the Nishimori condition many calculations simplify and can be done exactly (for an example see Appendix B.3). Throughout this chapter we assume, unless it is stated, the Nishimori condition.

For background reading about statistical physics methods in general, Nishimori’s condition and its relevance to the current calculation we refer the reader to [Nis01].

3. Sourlas Codes

The code of Sourlas is based on the idea of using a linear operator \( \mathbf{G} \) (generator matrix) to transform a message vector \( \mathbf{s} \in \{0,1\}^N \) onto a higher dimensional vector \( \mathbf{t} \in \{0,1\}^M \). The encoded vector is \( \mathbf{t} = \mathbf{G}s \) (mod 2), each bit \( t_k \) being the Boolean sum of \( K \) message bits (parity-check). This vector is transmitted through a noisy channel and a corrupted \( M \) dimensional vector \( \mathbf{r} \) is received.

Decoding consists of producing an estimate \( \hat{\mathbf{s}} \) of the original message. This estimate can be generated by considering a probabilistic model for the communication system. Reduced (order \( N \)) time/space requirements for the encoding process and the existence of fast (polynomial time) decoding algorithms are guaranteed by choosing sparse generator matrices, namely, a matrix \( \mathbf{G} \) with exactly \( K \) nonzero elements per row and \( C \) nonzero elements per column, where \( K \) and \( C \) are of order 1. The rate of such a code, in the case of unbiased messages, is evidently \( R = N/M \), as the total number of nonzero elements in \( \mathbf{G} \) is \( MK = NC \) the rate is also \( R = K/C \).

In the statistical physics language a binary message vector \( \mathbf{\xi} \in \{\pm 1\}^N \) is encoded to a higher dimensional vector \( \mathbf{J^0} \in \{\pm 1\}^M \) defined as \( J^0_{i_1i_2\ldots i_K} = \xi_{i_1}\xi_{i_2}\ldots\xi_{i_K} \), where \( M \) sets of \( K \) indices are randomly chosen. A corrupted version \( \mathbf{J} \) of the encoded message \( \mathbf{J^0} \) has to be decoded for retrieving the original message. The decoding process is the process
of calculating an estimate \( \hat{\xi} \) to the original message by minimizing a given expected loss \( \langle \mathcal{L}(\xi, \hat{\xi}) \rangle_{P(J|\xi)} \) averaged over the indicated probability distributions [Iba99]. The definition of the loss depends on the particular task; the overlap \( \mathcal{L}(\xi, \hat{\xi}) = \sum_j \xi_j \hat{\xi}_j \) can be used for decoding binary messages. As discussed in Section 2.2, an optimal estimator for this particular loss function is \( \hat{\xi}_j = \text{sign} \langle S_j \rangle_{P(J|\xi)} \) [Iba99], where \( \mathbf{S} \) is an \( N \) dimensional binary vector representing the dynamical variables of the decoding process and \( P(S_j | J) = \sum_{S_k, k \neq j} P(S | J) \) is the marginal posterior probability. Using Bayes theorem, the posterior probability can be written as:

\[
\ln P(S | J) = \ln P(J | S) + \ln P(S) + \text{const.} \tag{46}
\]

The likelihood \( P(J | S) \) has the form:

\[
P(J | S) = \prod_{\text{chosen sets}} \sum_{J_{(i_1 \ldots i_k)}} P(J_{(i_1 \ldots i_k)} | J_{(i_1 \ldots i_k)}^0) \times P(J_{(i_1 \ldots i_k)}^0 | S).
\tag{47}
\]

The term \( P(J_{(i_1 \ldots i_k)}^0 | S) \) models the deterministic encoding process being:

\[
P(J_{(i_1 \ldots i_k)}^0 | S) = \delta(J_{(i_1 \ldots i_k)}^0; S_{i_1} \ldots S_{i_K}).
\tag{48}
\]

The noisy channel is modeled by the term \( P(J_{(i_1 \ldots i_k)} | J_{(i_1 \ldots i_k)}^0) \). For the simple case of a memoryless binary symmetric channel (BSC), \( J \) is a corrupted version of the transmitted message \( J^0 \) where each bit is independently flipped with probability \( p \) during transmission, in this case [Sou94a]:

\[
\ln P(J_{(i_1 \ldots i_k)} | J_{(i_1 \ldots i_k)}^0) = \frac{1}{2} (1 + J_{(i_1 \ldots i_k)}^0) \ln P(J_{(i_1 \ldots i_k)} | +1) \\
+ \frac{1}{2} (1 - J_{(i_1 \ldots i_k)}^0) \ln P(J_{(i_1 \ldots i_k)} | -1) \\
= \text{const} + \frac{1}{2} \ln \left( \frac{1 - p}{p} \right) J_{(i_1 \ldots i_k)} J_{(i_1 \ldots i_k)}^0. \tag{49}
\]

Putting equations together we obtain the following Hamiltonian:

\[
\ln P(S | J) = - \beta N \mathcal{H}(S) \\
= \beta N \sum_{\mu} \mathcal{A}_\mu J_{\mu} \prod_{i \in \mathcal{L}(\mu)} S_i + \beta'_N \sum_{j=1}^N S_j, \tag{50}
\]

where a set of indices is denoted \( \mathcal{L}(\mu) = \{i_1, \ldots i_K\} \) and \( \mathcal{A} \) is a tensor with the properties \( \mathcal{A}_\mu \in \{0, 1\} \) and \( \sum_{\{i, j \in \mathcal{L}(\mu)\}} \mathcal{A}_\mu = C \forall \mu \), which determines the \( M \) components of the codeword \( J^0 \). The interaction term is at Nishimori’s temperature \( \beta_N = \frac{1}{2} \ln \left( \frac{1 - p}{p} \right) \) [Nis80, Iba99, Ruj93, Nis93], and \( \beta'_N = \frac{1}{2} \ln \left( \frac{1 - p}{p} \right) \) is the message prior temperature, namely, the prior distribution of message bits is assumed to be \( P(S_j = +1) = 1 - p_\xi \) and \( P(S_j = -1) = p_\xi \).

The decoding procedure translates to finding the thermodynamic spin averages for the system defined by the Hamiltonian (50) at a certain temperature (Nishimori temperature for optimal decoding); as the original message is binary, the retrieved message bits are given by the signs of the corresponding averages.
The performance of the error-correcting process can be measured by the overlap between actual message bits and their estimates for a given scenario characterized by code rate, corruption process and information content of the message. To assess the typical properties we average this overlap over all possible codes $\mathcal{A}$ and noise realizations (possible corrupted vectors $\mathbf{J}$) given the message $\mathbf{x}$ and then over all possible messages:

$$\rho = \frac{1}{N} \left< \sum_{i=1}^{N} \xi_i \left< \text{sign}(S_i) \right>_{\mathcal{A},\mathbf{J},\xi} \right>_{\xi}$$  \hfill (52)

Here $\text{sign}(S_i)$ is the sign of the spins thermal average corresponding to the Bayesian optimal decoding. The average error per bit is, therefore, given by $p_b = (1 - \rho)/2$.

The number of checks per bit is analogous to the spin system connectivity and the number of bits in each check is analogous to the number of spins per interaction. The code of Soulas has been studied in the case of extensive connectivity, where the number of bonds $C \sim \left( \frac{N-1}{K-1} \right)$ scales with the system size. In this case it can be mapped onto known problems in statistical physics such as the SK [KS78] ($K=2$) and Random Energy (REM) [Der81a] ($K \to \infty$) models. It has been shown that the REM saturates Shannon’s bound [Sou89]. However, it has a rather limited practical relevance as the choice of extensive connectivity corresponds to a vanishingly small code rate.

### 3.1. Lower bound for the probability of bit error

It has been observed in [MS00] that a sparse generator code can only attain vanishing probability of bit error if $K \to \infty$. This fact alone does not rule out the practical use of such codes as they can still be used if a controlled probability of error is allowed or as part of a concatenated code.

Before engaging in a relatively complex analysis, it is of theoretical interest to establish a detailed picture of how the minimum bit error attainable decays with $K$. This can be done in quite a simple manner suggested in [MS00]. Let us suppose that messages are unbiased and random and that the channel is a BSC of noise level $p$. Assume, without loss of generality, that the message $\xi_j = 1$ for all $j$ is sent. The bit error probability can be expressed as the sum $p_b = \sum_{j=1}^{N} p_b(l)$, where $p_b(l)$ represents the probability of decoding incorrectly any $l$ bits. Clearly $p_b \geq p_b(1)$.

The probability of decoding incorrectly a single bit can be easily evaluated. A bit $j$ engages in exactly $C$ interactions with different groups of $K$ bits in a way that their contribution to the Hamiltonian is:

$$\mathcal{H}_j = -S_j \sum_{\mu \in \mathcal{M}(j)} \sum_{i \in \mathcal{L}(\mu) \setminus j} J_{\mu} S_i,$$  \hfill (53)

where $\mathcal{M}(j)$ is the set of all index sets that contain $j$. If all bits but $j$ are set to $S_i = 1$, an error in $j$ only can be detected if its contribution to the Hamiltonian is positive; if $\sum_{\mu \in \mathcal{M}(j)} A_\mu J_{\mu} \leq 0$ the error is undetectable. The probability of error in a single bit is
therefore

\[ p_b(1) = P \left\{ \sum_{\mu \in \mathcal{M}(j)} J_\mu \leq 0 \right\}, \tag{54} \]

where \( \mathcal{A}_\mu = 1 \) for exactly \( C \) terms and \( J_\mu \) can be simply regarded as a random variable taking values \( +1 \) and \( -1 \) with probabilities \( 1 - p \) and \( p \) respectively, therefore:

\[ p_b \geq \sum_{l \in \mathbb{N}, C - 2l \leq 0} \frac{C!}{(C - l)! l!} (1 - p)^{C - l} p^l. \tag{55} \]

A lower bound for \( p_b \) in the large \( C \) regime can be obtained by using the DeMoivre-Laplace limit theorem [Fel50], writing:

\[ p_b \geq \frac{1}{2} \text{erfc} \left( \frac{(1 - p)C}{8p} \right) \approx \frac{4p}{\sqrt{\pi} (1 - p)C^2} \exp \left( -\frac{(1 - p)^2 C^2}{64p^2} \right), \tag{56} \]

where \( \text{erfc}(x) = \frac{2}{\sqrt{\pi}} \int_x^\infty du \exp(-u^2) \) and the asymptotic behavior is given in [GR94] (page 940). This bound implies that \( K \to \infty \) is a necessary condition for a vanishing bit error probability in sparse generator codes at finite rates \( R = K/C \).

### 3.2. Replica Theory for the Typical Performance of Sourlas Codes

In order to calculate the typical performance of Sourlas codes we employ the statistical physics technique known as replica theory.

To simplify analysis we use the gauge transformation [FHS78] \( S_i \to S_i \xi_i \) and \( J_{(i_1 \cdots i_K)} \to J_{(i_1 \cdots i_K)} \xi_1 \cdots \xi_K \) that maps any general message to the configuration defined as \( \xi_i^* = 1 \) \( \forall i \) (ferromagnetic configuration). By introducing the external field \( F \equiv \beta' / \beta \) we rewrite the Hamiltonian in the form:

\[ H(S) = -\sum_{(i_1 \cdots i_K)} \mathcal{A}_{(i_1 \cdots i_K)} J_{(i_1 \cdots i_K)} S_{i_1} \cdots S_{i_K} - F \sum_{j=1}^N \xi_j S_j, \tag{57} \]

With the gauge transformation, the bits of the uncorrupted encoded message become \( J^0_{(i_1 \cdots i_K)} = 1 \) and, for the BSC, the corrupted bits can be described as random variables with probability:

\[ P(J) = (1 - p) \delta(J - 1) + p \delta(J + 1), \tag{58} \]

where \( p \) is the channel flip rate. For deriving the typical properties we calculate the free-energy following the replica theory prescription:

\[ f = -\frac{1}{\beta} \lim_{N \to \infty} \frac{1}{N} \left. \frac{\partial}{\partial \beta} \right|_{n=0} \langle Z^n \rangle_{A, \xi, J}, \tag{59} \]

where \( \langle Z^n \rangle_{A, \xi, J} \) represents an analytical continuation in the interval \( n \in [0, 1] \) of the replicated partition function:

\[ \langle Z^n \rangle_{A, \xi, J} = \text{Tr}_{\{S_i^n\}} \left\{ e^{\beta F \sum_{\alpha, \beta} \xi_\alpha S_{i_\alpha}^n + \beta \sum_{\alpha, \beta} \mathcal{A}_\alpha J_\beta S_{i_\alpha}^n S_{i_\beta}^n} \right\}_{A, J, \xi}. \tag{60} \]
The overlap $\rho$ can be rewritten using gauged variables as:

$$\rho = \frac{1}{N} \sum_{l=1}^{N} \left\langle \left( \frac{\text{sign} (S_i)}{A(i, \xi^*)} \right)_{\xi^*} \right\rangle,$$

where $\xi^*$ denotes the transformation of a message $\xi$ into the ferromagnetic configuration.

To compute the replicated partition function we closely follow [WS87a]. We average uniformly over all codes $A$ such that $\sum_{(i_1, i_2, \ldots, i_K)} A(i_1, \ldots, i_K) = C \forall i$ to find:

$$\langle \mathcal{Z}^n \rangle_{A, \xi, J} = \exp \left\{ N \text{ Extr}_{q, \hat{q}} \left[ C - \frac{C}{K} + \frac{C}{K} \left( \sum_{l=0}^{n} T_l \sum_{(a_1, \ldots, a_l)} q_{a_1, \ldots, a_l}^K \right) \right] \right\},$$

where $T_l = \langle \tanh^l (\beta J) \rangle_l$, as in [VB85], $q_0 = 1$ and $\text{Extr}_{q, \hat{q}} f(q, \hat{q})$ denotes the extremum of $f$ (details in Appendix A.1). At the extremum of (62) the order parameters acquire a form similar to those of [WS87a]:

$$\hat{q}_{a_1, \ldots, a_l} = T_l q_{a_1, \ldots, a_l}^{-1}$$

$$q_{a_1, \ldots, a_l} = \left\langle \left( \prod_{l=1}^{l} S_{a_l}^l \right) \left( \sum_{l=0}^{n} \sum_{(a_1, \ldots, a_l)} \hat{q}_{a_1, \ldots, a_l} S_{a_1}^1 \cdots S_{a_l}^l \right)^{-1} \right\rangle_{\chi},$$

where

$$\chi = \langle e^{\beta F \xi \sum S_{a_l}^l} \rangle_{\xi} \left( \sum_{l=0}^{n} \sum_{(a_1, \ldots, a_l)} \hat{q}_{a_1, \ldots, a_l} S_{a_1}^1 \cdots S_{a_l}^l \right)^C,$$

and $\langle \cdots \rangle_{\chi} = \text{Tr}_{\{S_{a_l}^l\}} [\langle \cdots \rangle_{\chi}]/\text{Tr}_{\{S_{a_l}^l\}} [\langle \cdots \rangle_{\chi}]$.

To compute the partition function it is necessary to assume a replica symmetric (RS) ansatz. It can be done by introducing auxiliary fields $\pi(x)$ and $\hat{\pi}(y)$ (see also [WS87a]):

$$\hat{q}_{a_1, \ldots, a_l} = \int dy \hat{\pi}(y) \tanh^l (\beta y),$$

$$q_{a_1, \ldots, a_l} = \int dx \pi(x) \tanh^l (\beta x)$$

for $l = 1, 2, \ldots$

Plugging (65) into the replicated partition function (62), taking the limit $n \to 0$ and using Eq.(59) (see Appendix A.2 for details):

$$f = -\frac{1}{\beta} \text{Extr}_{\pi, \hat{\pi}} \left\{ \alpha \ln \cosh \beta \right\}$$
\[
+ \alpha \int \left[ \prod_{l=1}^{K} dx_l \, \pi(x_l) \right] \left\langle \ln \left[ 1 + \tanh \beta J \, \prod_{j=1}^{K} \tanh \beta x_j \right] \right\rangle_j \\
- C \int dx \, dy \, \pi(x) \, \widehat{\pi}(y) \, \ln \left[ 1 + \tanh \beta x \, \tanh \beta y \right] \\
- C \int dy \, \widehat{\pi}(y) \, \ln \cosh \beta y \\
+ \int \left[ \prod_{l=1}^{C} dy_l \, \widehat{\pi}(y_l) \right] \left\langle \ln \left[ 2 \cosh \beta \left( \sum_{j=1}^{C} y_j + F \xi \right) \right] \right\rangle_j, \\
\]

where \( \alpha = C/K \). The saddle-point equations obtained by calculating functional variations of Eq.(66) provide a closed set of relations between \( \pi(x) \) and \( \widehat{\pi}(y) \)

\[
\pi(x) = \int \left[ \prod_{l=1}^{C-1} dy_l \, \widehat{\pi}(y_l) \right] \left\langle \delta \left[ x - \sum_{j=1}^{C-1} y_j - F \xi \right] \right\rangle_x, \\
\widehat{\pi}(y) = \int \left[ \prod_{l=1}^{K-1} dx_l \, \pi(x_l) \right] \left\langle \delta \left[ y - \text{atanh} \left( \frac{\tanh \beta J \, \prod_{j=1}^{K-1} \tanh \beta x_j}{\beta} \right) \right] \right\rangle_y. \\
\]

Later we will show that this self-consistent pair of equations can be seen as a mean field description of probability propagation decoding.

Using the RS ansatz one can find that the local field distribution is (see Appendix A.3):

\[
P(h) = \int \left[ \prod_{l=1}^{C} dy_l \, \widehat{\pi}(y_l) \right] \left\langle \delta \left[ h - \sum_{j=1}^{C} y_j - F \xi \right] \right\rangle_y, \\
\]

where \( \widehat{\pi}(y) \) is given by the saddle-point equations (67).

The overlap (52) can be calculated using:

\[
\rho = \int dh \, \text{sign}(h) \, P(h). \\
\]

The code performance is assessed by assuming a prior distribution for the message, solving the saddle-point equations (67) numerically and then computing the overlap.

For Eq.(66) to be valid, the fixed point given by (67) must be stable and the related entropy must be non-negative. Instabilities within the RS space can be probed by calculating second functional derivatives at the extremum defining the free-energy (66). The solution is expected to be unstable within the space of symmetric replicas for sufficiently low temperatures (large \( \beta \)). For high temperatures we can expand the above expression around small \( \beta \) values to find the stability condition:

\[
\langle J \rangle_J \langle x \rangle_x^{K-2} \geq 0 \\
\]

The average \( \langle x \rangle_x = \int dx \, \pi(x) \, x \) vanishes in the paramagnetic phase and is positive (non-zero when \( K \) is even) in the ferromagnetic phase, satisfying the stability condition. We now restrict our study to the unbiased case \( (F = 0) \), which is of practical relevance, since it is always possible to compress a biased message to an unbiased one.
For the case $K \to \infty$, $C = \alpha K$ we can obtain solutions to the saddle-point equations at arbitrary temperatures. The first saddle-point equation (67) can be approximated by:

$$x = \sum_{l=1}^{C-1} y_l \approx (C - 1) \langle y \rangle_\pi = (C - 1) \int dy \, \hat{\pi}(y).$$  \hspace{1cm} (71)

If $\langle y \rangle_\pi = 0$ (paramagnetic phase) then $\pi(x)$ must be concentrated at $x = 0$ implying that $\pi(x) = \delta(x)$ and $\hat{\pi}(y) = \delta(y)$ are the only possible solutions. Equation (71) also implies that $x \approx \mathcal{O}(K)$ in the ferromagnetic phase.

Using Eq. (71) and the second saddle-point equation (67) we find a self-consistent equation for the mean field $\langle y \rangle_\pi$:

$$\langle y \rangle_\pi = \left\langle \frac{1}{\beta} \text{atanh} \left[ \tanh(\beta J) \tanh(\beta (C - 1) \langle y \rangle_\pi) \right]^{K-1} \right\rangle_B.$$  \hspace{1cm} (72)

For the BSC we average over the distribution (58). Computing the average, using $C = \alpha K$ and rescaling the temperature $\beta = \tilde{\beta}(\ln K)/K$, we obtain in the limit $K \to \infty$:

$$\langle y \rangle_\pi \approx (1 - 2p) \left[ \tanh(\tilde{\beta} \alpha \langle y \rangle_\pi \ln(K)) \right]^K,$$  \hspace{1cm} (73)

where $p$ is the channel flip probability. The mean field $\langle y \rangle_\pi = 0$ is always a solution to this equation (paramagnetic solution); at $\beta_c = \ln(K)/(2\alpha K(1 - 2p))$ an extra non-trivial ferromagnetic solution emerges with $\langle y \rangle_\pi = 1 - 2p$. The connection with the overlap $\rho$ is given by Eqs.(68) and (69) implying that $\rho = 1$ for the ferromagnetic solution. It is remarkable that the temperature where the ferromagnetic solution emerges is $\beta_c \sim \mathcal{O}(\ln(K)/K)$. Paramagnetic-ferromagnetic barriers that emerge at reasonably high temperatures, in a simulated annealing process, implying metastability and, consequently, a very slow convergence. It seems to advocate the use of small $K$ values in practical applications. For $\beta > \beta_c$ both paramagnetic and ferromagnetic solutions exist.

The ferromagnetic free-energy can be obtained from Eq.(66) using Eq.(71), resulting in $f_{\text{Ferro}} = -\alpha(1 - 2p)$. The corresponding entropy is $s_{\text{Ferro}} = 0$. The paramagnetic free-energy is obtained by plugging $\pi(x) = \delta(x)$ and $\hat{\pi}(y) = \delta(y)$ into Equation (66):

$$f_{\text{Para}} = -\frac{1}{\beta} (\alpha \ln \cosh \beta + \ln 2),$$  \hspace{1cm} (74)

$$s_{\text{Para}} = \alpha(\ln \cosh \beta - \beta \tanh \beta) + \ln 2.$$  \hspace{1cm} (75)

Paramagnetic solutions are unphysical for $\alpha > (\ln 2)/[\beta \tanh \beta - \ln(\cosh \beta)]$, since the corresponding entropy is negative. To complete the picture of the phase diagram we have to introduce a replica symmetry breaking scenario that yields sensible physics.

In general, to construct a symmetry breaking solution in finite connectivity systems (see [Mon98b, FLRTZ01]) is a difficult task. We choose as a first approach an one-step replica symmetry breaking scheme, known as the frozen spins solution, that yields exact results for the REM [GM84, Par80].

We assume that ergodicity breaks in such a way that the space of configurations is divided in $n/m$ islands. Inside each of these islands there are $m$ identical configurations,
implying that the system can freeze in any of \( n/m \) microstates. Therefore, in the space of replicas we have the following situation:

\[
\frac{1}{N} \sum_{j=1}^{N} S_j^{\alpha} S_j^{\beta} = 1 \quad \text{if} \quad \alpha \text{ and } \beta \text{ are in the same island}
\]

\[
\frac{1}{N} \sum_{j=1}^{N} S_j^{\alpha} S_j^{\beta} = q \quad \text{otherwise.}
\]  

(76)

By assuming the above structure the replicated partition function has the form:

\[
\langle Z_{RSB}^n \rangle_{A,\xi,J} = \left\langle \text{Tr}_{\{s_j^n\}} \exp \left(-\beta \sum_{\alpha=1}^{n} \mathcal{H}(S^{\alpha}) \right) \right\rangle_{A,\xi,J} = \left\langle \text{Tr}_{\{s_j^n, s_j^{n/m}\}} \exp \left(-\beta m \sum_{\alpha=1}^{n/m} \mathcal{H}(S^{\alpha}) \right) \right\rangle_{A,\xi,J} = \left\langle \prod_{\alpha} \text{Tr}_{\{s_j^{n/m}\}} \exp \left(-\beta m \mathcal{H}(S^{\alpha}) \right) \right\rangle_{A,\xi,J} = \frac{1}{m} \langle \ln Z_{RS}(\beta m) \rangle_{A,\xi,J}.
\]  

(77)

where in the first line we have used the ansatz with \( n/m \) islands with \( m \) identical configurations in each and in the last step we have used that the overlap between any two different islands is \( q \). From (77) we have:

\[
\langle \ln Z_{RSB}(\beta) \rangle_{A,\xi,J} = \frac{\partial}{\partial n} \left. \langle Z_{RSB}^n(\beta) \rangle_{A,\xi,J} \right|_{n=0} = \frac{1}{m} \langle \ln Z_{RS}(\beta m) \rangle_{A,\xi,J}.
\]  

(78)

The number of configurations per island \( m \) must extremize the free-energy, therefore, we have:

\[
\frac{\partial}{\partial m} \langle \ln Z_{RSB}(\beta) \rangle_{A,\xi,J} = 0,
\]  

(79)

what is equivalent to

\[
s_{RS}(\beta_g) = -\tilde{\beta}^2 \left. \frac{\partial^2}{\partial \beta^2} \right|_{\beta=\beta_g} \left[ \frac{1}{\beta} \langle \ln Z_{RS}(\tilde{\beta}) \rangle_{A,\xi,J} \right] = 0,
\]  

(80)

where we introduced \( \tilde{\beta} = \beta m \). In this way \( m = \beta_g / \beta \), with \( \beta_g \) being a root of the replica symmetric paramagnetic entropy (74), satisfying:

\[
\alpha (\ln (\cosh \beta_g) - \beta_g \tanh \beta_g) + \ln 2 = 0
\]  

(81)

The RSB-spin glass free-energy is given by \( f_{RAB} \) (74) at temperature \( \beta_g \):

\[
f_{RSB-SG} = -\frac{1}{\beta_g} (\alpha \ln (\cosh \beta_g) + \ln 2),
\]  

(82)

consequently the entropy is \( s_{RSB-SG} = 0 \). In Fig. 8 we show the phase diagram for a given code rate \( R \) in the plane of temperature \( T \) and noise level \( p \).
3.3. Shannon’s bound

The channel coding theorem asserts that up to a critical code rate $R_c$, which equals the channel capacity (Shannon’s bound), it is possible to recover information with arbitrarily small probability of error. For the BSC:

$$R_c = \frac{1}{\alpha_c} = 1 + p \log_2 p + (1 - p) \log_2 (1 - p).$$  \hspace{1cm} (83)

The code of Sourlas, in the case where $K \to \infty$ and $C \sim O(N^K)$, can be mapped onto the REM and has been shown to saturates the channel capacity in the limit $R \to 0$ [Sour89]. Shannon’s bound can also be attained by Sourlas code at zero temperature for $K \to \infty$ but with connectivity $C = \alpha K$. In this limit the model is analogous to the diluted REM analyzed by Saakian [Saa98]. The errorless phase is manifested in a ferromagnetic phase with total alignment $(\rho = 1)$, only attainable for infinite $K$. Up to a certain critical noise level, a noise level increase produces ergodicity breaking leading to a spin glass phase where the misalignment is maximal $(\rho = 0)$. The ferromagnetic-spin glass transition corresponds to the transition from errorless decoding to decoding with errors described by the channel coding theorem. A paramagnetic phase is also present when the transmitted information is insufficient to recover the original message $(R > 1)$. 

Figure 8. Phase diagram in the plane of temperature $T$ versus noise level $p$ for $K \to \infty$ and $C = \alpha K$, with $\alpha = 4$. The dotted line indicates the Nishimori temperature $T_N$. Full lines represent phase coexistence. The critical noise level is $p_c$. The necessary condition for stability of the ferromagnetic phase within the replica symmetric space is satisfied above the dashed line.
At zero temperature saddle-point equations (67) can be rewritten as:

\[
\pi(x) = \int \prod_{l=1}^{C-1} dy_l \hat{\pi}(y_l) \delta \left[ x - \sum_{j=1}^{C-1} y_j \right] 
\]

\[
\hat{\pi}(y) = \int \prod_{l=1}^{K-1} dx_l \pi(x_l) 
\]

\[
\times \left\langle \delta \left[ y - \text{sign}(J \prod_{l=1}^{K-1} x_l) \min(|x_1|, \ldots, |x_{K-1}|) \right] \right\rangle_J ,
\]

The solutions for these saddle-point equations may result in very structured probability distributions. As an approximation we choose the simplest self-consistent family of solutions which are, since \( J = \pm 1 \), given by:

\[
\hat{\pi}(y) = p_+ \delta(y - 1) + p_0 \delta(y) + p_- \delta(y + 1) 
\]

\[
\pi(x) = \sum_{l=1}^{C-1} T_{[p_+, p_0, C-1]}(l) \delta(x - l),
\]

with

\[
T_{[p_+, p_0, C-1]}(l) = \sum_{\{k,h,m\}} \frac{(C-1)!}{k! h! m!} p_+^k p_0^h p_-^m ,
\]

where the prime indicates that \( k, h, m \) are such that \( k - h = l; k + h + m = C - 1 \). Evidence for this simple ansatz comes from Monte-Carlo integration of Eq.(67) at very low temperatures, that shows solutions comprising three dominant peaks and a relatively weak regular part. Plugging this ansatz (86) in the saddle-point equations we write a closed set of equations in \( p_\pm \) and \( p_0 \) that can be solved numerically.

Solutions are of three types: ferromagnetic \( (p_+ > p_-) \), paramagnetic \( (p_0 = 1) \) and replica symmetric spin glass \( (p_- = p_+) \). Computing free-energies and entropies enables one to construct the phase diagram. At zero temperature the paramagnetic free-energy is \( f_{\text{PARA}} = -\alpha \) and the entropy is \( s_{\text{PARA}} = (1 - \alpha) \ln 2 \), this phase is physical only for \( \alpha < 1 \), what is expected since it corresponds exactly to the regime where the transmitted information is insufficient to recover the actual message \( (R > 1) \).

The ferromagnetic free-energy does not depend on the temperature, having the form \( f_{\text{FERRO}} = -\alpha (1 - 2p) \) with entropy \( s_{\text{FERRO}} = 0 \). We can find the ferromagnetic spin glass coexistence line that corresponds to the maximum performance of a Sourlas code by equating Eq. (82) and \( f_{\text{FERRO}} \). Observing that \( \beta_\alpha = \beta_N(p_\alpha) \) (as seen in Fig. 8) we find that this transition coincides with the channel capacity (83). It is interesting to note that in the large \( K \) regime both RS-ferromagnetic and RSB-spin glass free-energies (for \( T < T_g \) do not depend on the temperature, it means that Shannon’s bound is saturated also for finite temperatures up to \( T_g \). In Fig.9 we represent the complete zero temperature phase diagram.

The bound obtained depends on the stability of the ferromagnetic and paramagnetic solutions within the space of symmetric replicas at zero temperature. Instabilities are
found in the ferromagnetic phase for \( p > 0 \). These instabilities within the replica symmetric space puts in question our result of saturating Shannon’s bound, since a correction to the ferromagnetic solution could change the ferromagnetic-spin glass transition line. However, the instability vanishes for high temperatures, which supports the ferromagnetic-spin glass transition line obtained and possible saturation of the bound in some region.

Shannon’s bound can only be attained in the limit \( K \to \infty \); however, there are some possible drawbacks in using high \( K \) values due to large barriers which are expected to occur between the paramagnetic and ferromagnetic phases. We now consider the finite \( K \) case, for which we can solve the RS saddle-point equations (67) for arbitrary temperatures using Monte-Carlo integration. We can also obtain solutions for the zero temperature case using Eqs.(86) iteratively.

It has been shown that \( K > 2 \) extensively connected models [GM84] exhibit Parisi-type order functions with similar discontinuous structure as found in the \( K \to \infty \) case; it was also shown that the one-step RSB frozen spins solution, employed to describe the spin glass phase, is locally stable within the complete replica space and zero field (unbiased messages case) at all temperatures. We, therefore, assume that the ferromagnetic-spin glass transition for \( K > 2 \) is described by the frozen spins RSB solution.

At the top of Fig.10 we show the zero temperature overlap \( \rho \) as a function of the noise level \( p \) at code rate \( R = 1/2 \) obtained by using the three peaks ansatz. Note that the RSB spin glass phase dominates for \( p > p_c \) (see bottom of Fig.10). In the
In the bottom figure we plot RS free-energies and RSB frozen spins free-energy, from which we determine the noise level $p_n$ for coexistence of ferromagnetic and spin-glass phases (pointed by an arrow). Above the transition, the system enters in a paramagnetic or RS spin glass phase with free-energies for $K = 3, 4, 5$ and $6$ that are lower than the RSB spin glass free-energy; nevertheless, the entropy is negative and these free-energies are therefore unphysical. It is remarkable that the coexistence value does not change significantly for finite $K$ in comparison to infinite $K$. Remind that Shannon’s bound cannot be attained for finite $K$, since $\rho \to 1$ ($p_n \to 0$) only if $K \to \infty$.

It is known that the $K = 2$ model with extensive connectivity (SK model) requires a full Parisi solution to recover the concavity of the free-energy [MPV87]. No stable solution is known for the intensively connected model (Viana-Bray model). Probability propagation only solves the decoding problem approximately, the approximated solutions are similar to those obtained by supposing replica symmetry. Thus, the theoretical relevance of the RS results for $K = 2$ are to be evaluated by comparison with simulations of probability propagation decoding.

### 3.4. Decoding with probability propagation

The decoding task consists of evaluating estimates of the form $\hat{\xi}_j = \text{sign}(S_j)P(\hat{\xi}_j|J)$. The marginal posterior $P(S_j \mid J) = \sum_{s_i, i \neq j} P(S \mid J)$ can be, in principle, be calculated
simply by using Bayes theorem and a proper model for the encoding and corruption processes (namely, coding by a sparse generator matrix with \(K\) bit long parity-checks and a memoryless BSC channel) to write:

\[
P(S_j \mid J) = \frac{1}{P(J)} \sum_{S_i \neq J} \prod_{\mu} P(J_\mu \mid S_{i_\mu} \cdots S_{i_K}) \prod_{i=1}^{N} P(S_i),
\]

where \(P(J)\) is a normalization dependent on \(J\) only. A brute force evaluation of the above marginal on a space of binary vectors \(S \in \{\pm 1\}^N\) with \(M\) checks would take \((M + N + 1)2^N\) operations, what becomes infeasible very quickly. To illustrate how dramatically the computational requirements increase, assume a code of rate \(R = 1/2\), if \(N = 10\) the number of operations required is 31744, if one increases the message size to \(N = 1000\), \(3 \times 10^{301}\) operations are required! Monte-Carlo sampling is an alternative to brute force evaluation; it consists of generating a number (much less than \(2^N\)) of typical vectors \(S\) and using this to estimate the marginal posterior, however the sample size required can prove to be equally prohibitive.

As a solution to these resource problems, we can explore the structure of (88) to devise an algorithm that produces an approximation to \(P(S_j \mid J)\) in \(O(N)\) operations. We start by concentrating on one particular site \(S_j\); this site interacts directly with a number of other sites through \(C\) couplings denoted by \(J_{(i_1 \cdots i_K)}\) and \(\{J_\mu\} = J_{\mu(1)}, \cdots, J_{\mu(C-1)}.\) Suppose now that we isolate only the interaction via coupling \(J_{(i_1 \cdots i_K)},\) if the bipartite Bayesian network representing the dependencies in the problem is a tree, it is possible to write:

\[
P(S_j \mid J_{(i_1 \cdots i_K)}) = \frac{P(S_j)}{P(J_{(i_1 \cdots i_K)})} \sum_{\{S_{i_1 \cdots S_{i_{K-1}}}\}} P(J_{(i_1 \cdots i_K)} \mid S_j, S_{i_1 \cdots S_{i_{K-1}}}) \\
\times \prod_{i=1}^{K-1} P(S_i \mid \{J_\mu : \mu \in \mathcal{M}(i)\}).
\]

Terms like \(P(S_i, \{J_\mu\})\) can be interpreted simply as updated priors for \(S_i.\) In a tree, these terms factorize like \(P(S_i \mid \{J_\mu\}) = \prod_{j=1}^{C-1} P(S_i, \{J_\mu(j)\})\) and a recursive relation can be obtained, introducing:

\[
Q_{i,j}^\nu = P(S_j = x \mid \{J_\mu : \mu \in \mathcal{M}(j) \setminus \nu\})
\]

and

\[
R_{i,j}^\nu = \sum_{\{S_i : i \in \mathcal{L}(\nu) \setminus j\}} P(J_\nu \mid S_j, \{S_i : i \in \mathcal{L}(\nu) \setminus j\}) \prod_{i \in \mathcal{L}(\nu) \setminus j} Q_{i,i}^\nu,
\]

where \(\mathcal{M}(j)\) is the set of couplings linked to site \(j\) and \(\mathcal{L}(\nu)\) is the set of sites linked to coupling \(\nu.\)

Equation (89) can be rewritten as:

\[
Q_{i,j}^\nu = a_{i,j} P(S_j = x) \prod_{\nu \in \mathcal{M}(j) \setminus \mu} R_{i,j}^\nu.
\]

Equations (91) and (92) can be solved iteratively, requiring \((2^K KC + 2C^2)NT\) operations with \(T\) being the (order 1) number of steps needed for convergence. These
computational requirements may be further reduced by using advanced Markov chain Monte-Carlo methods [Mac99].

An approximation to the marginal posterior (88) is obtained by counting the influence of all $C$ interactions over each site $j$ and using the assumed factorization property to write:

$$Q_j^x = a_j P(S_j = x) \prod_{\nu \in \mathcal{M}(j)} R^x_{\nu j}. \quad (93)$$

This is an approximation in the sense that the recursion obtained from (89) is only guaranteed to converge to the correct posterior if the system has a tree structure, i.e., every coupling appears only once as one goes backwards in the recursive chain.

By taking advantage of the normalization conditions for the distributions $Q^+_{\rho j} + Q^-_{\rho j} = 1$ and $R^+_{\rho j} + R^-_{\rho j} = 1$, one can change variables and reduce the number of equations by a factor of two $m_{\rho j} = Q^+_{\rho j} - Q^-_{\rho j}$ and $\tilde{m}_{\rho j} = R^+_{\rho j} - R^-_{\rho j}$.

The analogy with statistical physics can be exposed by first observing that:

$$P(J_\mu \mid S_j, \{S_i : i \in \mathcal{L}(\mu) \setminus j\}) \sim \exp \left(-\beta J_\mu \prod_{i \in \mathcal{L}(\mu)} S_i \right). \quad (94)$$

That can be also written in the more convenient form:

$$P(J_\mu \mid S_j, \{S_i : i \in \mathcal{L}(\mu) \setminus j\}) \sim \frac{1}{2} \cosh(\beta J_\mu) \left(1 + \tanh(\beta J_\mu) \prod_{j \in \mathcal{L}(\mu)} S_j \right). \quad (95)$$

Plugging Eq. (95) for the likelihood in equations (92), using the fact that the prior probability is given by $P(S_j) = \frac{1}{2}(1 + \tanh(\beta_N S_j))$ and computing $m_{\rho j}$ and $\tilde{m}_{\rho j}$ (see Appendix A.6) one obtains:

$$\tilde{m}_{\rho j} = \tanh(\beta J_\mu) \prod_{i \in \mathcal{L}(\mu) \setminus j} m_{\rho i},$$

$$m_{\rho j} = \tanh \left( \sum_{\nu \in \mathcal{M}(\mu) \setminus \mu} \text{atanh}(\tilde{m}_{\nu j}) + \beta' \right). \quad (96)$$

The pseudo-posterior can then be calculated:

$$m_j = \tanh \left( \sum_{\nu \in \mathcal{M}(\mu) \setminus \mu} \text{atanh}(\tilde{m}_{\nu j}) + \beta' \right), \quad (97)$$

providing Bayes optimal decoding $\hat{\xi}_j = \text{sign}(m_j)$.

Equations (96) depend on the received message $J$. In order to make the analysis message independent, we can use a gauge transformation $\tilde{m}_{\rho j} \rightarrow \xi_j \tilde{m}_{\rho j}$ and $m_{\rho j} \rightarrow \xi_j m_{\rho j}$ to write:

$$\tilde{m}_{\rho j} = \tanh(\beta J) \prod_{i \in \mathcal{L}(\mu) \setminus j} m_{\rho i},$$

$$m_{\rho j} = \tanh \left( \sum_{\nu \in \mathcal{M}(\mu) \setminus \mu} \text{tanh}^{-1}(\tilde{m}_{\nu j}) + \beta' \xi_j \right). \quad (98)$$
Figure 11. Overlap as a function of the flip probability \( p \) for decoding using TAP equations for \( K = 2 \). From the bottom: Monte-Carlo solution of the RS saddle-point equations for unbiased messages (\( \rho_\xi = 0.5 \)) at \( T = 0.26 \) (line) and 10 independent runs of TAP decoding for each flip probability (plus signs), \( T = 0.26 \) and biased messages (\( \rho_\xi = 0.1 \)) at the Nishimori temperature \( T_N \).

In the new variables, a decoding success corresponds to \( \hat{m}_{\mu j} > 0 \) and \( m_{\mu j} = 1 \) for all \( \mu \) and \( j \). By transforming these variables as \( \hat{m} = \tanh(\beta y) \) and \( m = \tanh(\beta x) \) and considering the actual message and noise as quenched disorder, Eqs. (98) can be rewritten as:

\[
y = \frac{1}{\beta} \left\langle \tanh^{-1} \left( \tanh(\beta J) \prod_{j=1}^{K-1} \tanh(\beta x_j) \right) \right\rangle_j
\]

\[
x = \left\langle \sum_{j=1}^{C-1} y_j + \xi F \right\rangle_\xi.
\]

(99)

For a large number of iterations, one can expect the ensemble of probability networks to converge to an equilibrium distribution where \( \hat{m} \) and \( m \) are random variables sampled from distributions \( \hat{\phi}(y) \) and \( \phi(x) \) respectively. The above relations lead to a dynamics of the distributions \( \hat{\phi}(y) \) and \( \phi(x) \), that is exactly as the one obtained when solving iteratively RS saddle-point equations (67). The probability distributions \( \hat{\phi}(y) \) and \( \phi(x) \) can be, therefore, identified with \( \hat{\pi}(y) \) and \( \pi(x) \) respectively and the RS solutions correspond to decoding a generic message using probability propagation averaged over an ensemble of different codes, noise and signals.

Equations (96) are now used to show the agreement between the simulated decoding and analytical calculations. For each run, a fixed code is used to generate 200000 bit codewords from 10000 bit messages, corrupted versions of the codewords are then
decoded using (96). Numerical solutions for 10 individual runs are presented in Figs.11 and 12, initial conditions are chosen as \( \hat{n}_{\mu j} = 0 \) and \( m_{\mu j} = \tanh(\beta'_{N} \epsilon) \) reflecting the prior beliefs. In Fig.11 we show results for \( K = 2 \) and \( C = 4 \) in the unbiased case, at code rate \( R = 1/2 \) (prior probability \( P(S_j = +1) = p_{\xi} = 0.5 \)) and low temperature \( T = 0.26 \) (we avoided \( T = 0 \) due to numerical difficulties). Solving the saddle-point equations (67) numerically using Monte-Carlo integration methods we obtain solutions with good agreement to simulated decoding. In the same figure we show the performance for the case of biased messages \( (P(S_j = +1) = p_{\xi} = 0.1) \), at code rate \( R = 1/4 \). Also here the agreement with Monte-Carlo integrations is satisfactory. The third curve in Fig.11 shows the performance for biased messages at the Nishimori temperature \( T_N \), as expected, it is far superior compared to low temperature performance and the agreement with Monte-Carlo results is even better.

In Fig.12 we show the results obtained for \( K = 5 \) and \( C = 10 \). For unbiased messages the system is extremely sensitive to the choice of initial conditions and does not perform well on average even at the Nishimori temperature. For biased messages \( (p_{\xi} = 0.1, R = 1/4) \) results are far better and in agreement with Monte-Carlo integration of the RS saddle-point equations.
The experiments show that probability propagation methods may be used successfully for decoding Sourlas-type codes in practice, and provide solutions that are consistent with the RS analytical solutions.

4. Gallager Codes

In 1962 Gallager [Gal62] proposed a coding scheme which involves sparse linear transformations of binary messages in the decoding stage, while encoding uses a dense matrix. His proposal was overshadowed by convolutional codes due to computational limitations. The best computer available to Gallager in 1962 was an IBM 7090 costing US$ 3 million and with disk capacity of 1 Megabyte, while convolutional codes, in comparison, only demanded a simple system of shift registers to process one byte at a time.

Gallager codes have been rediscovered recently by MacKay and Neal that proposed a closely related code [MN95] to be discussed in Section 5. This almost coincided with the breakthrough discovery of high performance Turbo codes [BGT93]. Variations of Gallager codes have displayed performance comparable (sometimes superior) to Turbo codes [Dav98, Dav99], qualifying them as state-of-the-art codes.

A Gallager code is defined by a binary matrix $A = [C_1 \mid C_2]$, concatenating two very sparse matrices known to both sender and receiver, with $C_2$ (of dimensionality $(M - N) \times (M - N)$) being invertible and $C_1$ of dimensionality $(M - N) \times N$. A non-systematic Gallager code is defined by a random matrix $A$ of dimensionality $(M - N) \times M$. This matrix can, in general, be organized in a systematic form by eliminating a number $\epsilon \sim O(1)$ of rows and columns.

Encoding refers to the generation of an $M$ dimensional binary vector $t \in \{0, 1\}^M$ ($M > N$) from the original message $\xi \in \{0, 1\}^N$ by

$$t = G^T \xi \pmod{2},$$

where all operations are performed in the field $\{0, 1\}$ and are indicated by (mod 2). The generator matrix is

$$G = [I \mid C_2^{-1}C_1] \pmod{2},$$

where $I$ is the $N \times N$ identity matrix, implying that $AG^T \pmod{2} = 0$ and that the first $N$ bits of $t$ are set to the message $\xi$. Note that the generator matrix is dense and each transmitted parity-check carries information about an $O(N)$ number of message bits. In regular Gallager codes the number of non-zero elements in each row of $A$ is chosen to be exactly $K$. The number of elements per column is then $C = (1 - \rho)K$, where the code rate is $R = N/M$ (for unbiased messages). The encoded vector $t$ is then corrupted by noise represented by the vector $\zeta \in \{0, 1\}^M$ with components independently drawn from $P(\zeta) = (1 - p)\delta(\zeta) + p\delta(\zeta - 1)$. The received vector takes the form

$$r = G^T \xi + \zeta \pmod{2}.$$
Decoding is carried out by multiplying the received message by the matrix $A$ to produce the syndrome vector
\[ z = Ar = A\zeta \pmod{2}, \] (103)
from which an estimate $\hat{\zeta}$ for the noise vector can be produced. An estimate for the original message is then obtained as the first $N$ bits of $r + \hat{\zeta} \pmod{2}$. The Bayes optimal estimator (also known as marginal posterior maximizer, MPM) for the noise is defined as $\hat{\zeta}_j = \arg\max_{\zeta_j} P(r_j \mid z)$. The performance of this estimator can be measured by the bit error probability $p_b = 1 - 1/M \sum_{j=1}^{M} \delta[\hat{\zeta}_j; \zeta_j]$, where $\delta[;]$ is the Kronecker delta. Knowing the matrices $C_2$ and $C_1$, the syndrome vector $z$ and the noise level $p$ it is possible to apply Bayes theorem and compute the posterior probability
\[ P(\tau \mid z) = \frac{1}{Z} \chi[z = Ar \pmod{2}] P(\tau), \] (104)
where $\chi[X]$ is an indicator function providing 1 if $X$ is true and 0 otherwise. To compute the MPM one has to compute the marginal posterior $P(\tau_j \mid z) = \sum_{i \neq j} P(\tau \mid z)$, which in general requires $O(2^M)$ operations, thus becoming impractical for long messages. To solve this problem we can take advantage of the sparseness of $A$ and use probability propagation for decoding, requiring $O(M)$ operations to perform the same task.

### 4.1. Upper bound on achievable rates

It was pointed by MacKay in [Mac99] that an upper bound for rates achievable for Gallager codes can be found from information theoretic arguments. This upper bound is based on the fact that each bit of the syndrome vector $z = A\zeta \pmod{2}$ is a sum of $K$ noise bits independently drawn from a binomial distribution $P(\zeta)$ with $P(\zeta = 0) = 1 - p$. The probability of $z_j = 1$ is $p_1^j(K) = \frac{1}{2} - \frac{1}{2}(1 - 2p)^K$ (see Appendix C.1 for details). Therefore, the maximal information content in the syndrome vector is $(M - N)H_2(p_1^j(K))$ (in bits or shannons), where $H_2(x)$ is the binary entropy. In the decoding process one has to extract information from the syndrome vector in order to reconstruct a noise vector $\zeta$ which has an information content of $MH_2(p)$. It clearly means that a necessary condition for successful decoding is:

\[
(M - N)H_2(p_1^j(K)) \geq MH_2(p) \\
(1 - R)H_2(p_1^j(K)) \geq H_2(p) \\
R \leq 1 - \frac{H_2(p)}{H_2(p_1^j(K))}.
\] (105)

In Fig.13a we plot this bound by fixing $K$ and finding the minimum value for $C$ such that $R = 1 - C/K$ verifies (105). Observe that as $K \to \infty$, $p_1^j(K) \to 1/2$ and $R \to 1 - H_2(p)$ that corresponds to Shannon’s bound.

In Fig.13b we plot the bound by fixing $C$ and finding the maximum $K$ such that $R = 1 - C/K$ satisfies (105), recovering the curves presented in [Mac99]. Note that $K \to \infty$ implies $C \to \infty$ and vice-versa. Gallager codes only can attain Shannon’s bound asymptotically in the limit of large $K$ or, equivalently, large $C$. 
4.2. Statistical physics formulation

The connection to statistical physics is made by replacing the field \( \{0, 1\} \) by Ising spins \( \{\pm 1\} \) and mod 2 sums by products [Sou89]. The syndrome vector acquires the form of a multi-spin coupling \( \mathcal{J}_\mu = \prod_{j \in \mathcal{L}(\mu)} \zeta_j \) where \( j = 1, \ldots, M \) and \( \mu = 1, \ldots, (M - N) \). The \( K \) indices of nonzero elements in the row \( \mu \) of \( A \) are given by \( \mathcal{L}(\mu) = \{ j_1, \ldots, j_K \} \), and in a column \( i \) are given by \( \mathcal{M}(i) = \{ \mu_1, \ldots, \mu_C \} \).

The following family of posterior probabilities can be introduced:

\[
P_\gamma(\tau \mid \mathcal{J}) = \frac{1}{Z} \exp \left[ -\beta \mathcal{H}_\gamma(\tau; \mathcal{J}) \right] \tag{106}
\]

\[
\mathcal{H}_\gamma(\tau; \mathcal{J}) = -\gamma \sum_{\mu=1}^{M-N} \left( \mathcal{J}_\mu \prod_{j \in \mathcal{L}(\mu)} \tau_j - 1 \right) - F \sum_{j=1}^{M} \tau_j.
\]

The Hamiltonian depends on hyper-parameters \( \gamma \) and \( F \). For optimal decoding, \( \gamma \) and \( F \) have to be set to specific values that best represent how the encoding process and corruption were performed (Nishimori condition [Iba99]). Therefore, \( \gamma \) must be taken to infinity to reflect the hard constraints in Eq.(104) and \( F = \text{atanh}(1 - 2p) \), reflecting the channel noise level \( p \). The temperature \( \beta \) must simultaneously be chosen to be the Nishimori temperature \( \beta_N = 1 \), that will keep the hyper-parameters in the correct value.

The disorder in (106) is trivial and can be gauged to \( \mathcal{J}_\mu \to 1 \) by using \( \tau_j \to \tau_j \zeta_j \). The resulting Hamiltonian is a multi-spin ferromagnet with finite connectivity in a random field \( \zeta_j F \):

\[
\mathcal{H}_\gamma^{\text{gauged}}(\tau; \zeta) = -\gamma \sum_{\mu=1}^{M-N} \left( \prod_{j \in \mathcal{L}(\mu)} \tau_j - 1 \right) - F \sum_{j=1}^{M} \zeta_j \tau_j. \tag{107}
\]

At the Nishimori condition \( \gamma \to \infty \) and the model is even simpler, corresponding
to a paramagnet with restricted configuration space on a non-uniform external field:

$$\mathcal{H}^{\text{gauged}}(\bm{\tau} \in \Omega; \bm{\zeta}) = -F \sum_{j=1}^{M} \zeta_j \tau_j, \quad (108)$$

where

$$\Omega = \{ \bm{\tau} : \prod_{j \in \mathcal{L}(\mu)} \tau_j = 1, \mu = 1, \cdots, M - N \}. \quad (109)$$

The optimal decoding process simply corresponds to finding local magnetizations at the Nishimori temperature $m_j = \langle \tau_j \rangle_{\beta N}$ and calculating Bayesian estimates as $\tilde{\tau}_j = \text{sgn}(m_j)$.

In the \{±1\} representation the probability of bit error, acquires the form

$$p_b = \frac{1}{2} - \frac{1}{2M} \sum_{j=1}^{M} \zeta_j \text{sgn}(m_j), \quad (110)$$

connecting the code performance with the computation of local magnetizations.

4.3. Replica theory

In this section we use the replica theory for analyzing the typical performance of Gallager codes along the same lines discussed for Sourlas codes. We start by rewriting the gauged Hamiltonian (107) in a form more suitable for computing averages over different codes:

$$\mathcal{H}^{\text{gauged}}_\gamma(\bm{\tau}; \bm{\zeta}) = -\gamma \sum_{(i_1 \cdots i_K)} A_{(i_1 \cdots i_K)} (\tau_{i_1} \cdots \tau_{i_K} - 1) - F \sum_{j=1}^{M} \zeta_j \tau_j, \quad (111)$$

where $A_{(i_1 \cdots i_K)} \in \{0, 1\}$ is a random symmetric tensor with the properties:

$$\sum_{(i_1 \cdots i_K)} A_{(i_1 \cdots i_K)} = M - N \quad \sum_{(i_1 \cdots i_K)} A_{(i_1 \cdots i_K)} = C \forall l, \quad (112)$$

that selects $M - N$ sets of indices (construction). The construction \{A_{(i_1 \cdots i_K)}\} and the noise vector $\bm{\zeta}$ are to be regarded as quenched disorder. As usual, the aim is to compute the free-energy:

$$f = -\frac{1}{\beta} \lim_{M \to \infty} \frac{1}{M} \langle \ln \mathcal{Z} \rangle_{\mathcal{A}, \bm{\zeta}}, \quad (113)$$

from which the typical macroscopic (thermodynamic) behavior can be obtained. The partition function $\mathcal{Z}$ is:

$$\mathcal{Z} = \text{Tr}_{\bm{\tau}} \exp \left(-\beta \mathcal{H}^{\text{gauged}}_\gamma(\bm{\tau}; \bm{\zeta})\right). \quad (114)$$

The free energy can be evaluated calculating following expression

$$f = -\frac{1}{\beta} \lim_{M \to \infty} \frac{1}{M} \frac{\partial}{\partial n} \bigg|_{n=0} \langle \mathcal{Z}^n \rangle_{\mathcal{A}, \bm{\zeta}}, \quad (115)$$
where
\[ \langle Z^n \rangle_{A, \zeta} = \sum_{\tau_1 \cdots \tau_n} \prod_{j=1}^M \left\langle \exp \left( F \zeta \beta \sum_{\alpha=1}^n \tau_{j}^\alpha \right) \right\rangle_{\zeta} \]
\[ \times \left\langle \prod_{(i_1 \cdots i_K)} \prod_{\alpha=1}^n \exp \left[ \beta \gamma A_{(i_1 \cdots i_K)} (\tau_{i_1}^\alpha \cdots \tau_{i_K}^\alpha - 1) \right] \right\rangle_A. \quad (116) \]

The average over constructions \( \langle \cdots \rangle_A \) takes the form:
\[ \langle \cdots \rangle_A = \frac{1}{N} \sum_{\{A\}} \prod_{j=1}^M \delta \left( \sum_{(i_1 \cdots i_K)} A_{(i_1 \cdots i_K)} - C \right) (\cdots) \]
\[ = \frac{1}{N} \sum_{\{A\}} \prod_{j=1}^M \left[ \int \frac{dZ_j}{2\pi i} \frac{1}{Z_j^{C+1}} Z_j^{\sum_{(i_1 \cdots i_K)} A_{(i_1 \cdots i_K)}} \right] (\cdots), \quad (117) \]

and the average \( \langle \cdots \rangle_{\zeta} \) over the noise is:
\[ \langle \cdots \rangle_{\zeta} = \sum_{\zeta=-1,1} (1 - p) \delta(\zeta - 1) + p \delta(\zeta + 1) (\cdots). \quad (118) \]

By computing the averages above and introducing auxiliary variables through the identity
\[ \int dq_{a_1 \cdots a_m} \delta \left( q_{a_1 \cdots a_m} - \frac{1}{M} \sum_{i} Z_i \tau_i^{a_1} \cdots \tau_i^{a_m} \right) = 1 \]
\[ \quad (119) \]
one finds, after using standard techniques (see Appendix B.1 for details), the following expression for the replicated partition function:
\[ \langle Z^n \rangle_{A, \zeta} = \frac{1}{N} \int \left( \frac{dq_{a_1}, dq_0}{2\pi i} \right) \left( \prod_{\alpha=1}^n \frac{dq_\alpha dq_\alpha}{2\pi i} \right) \]
\[ \times \exp \left[ \frac{MK}{K!} \sum_{m=0}^n \sum_{(a_1 \cdots a_m)} T_m q_{a_1 \cdots a_m} \right] \]
\[ - M \sum_{m=0}^n \sum_{(a_1 \cdots a_m)} q_{a_1 \cdots a_m} \tilde{q}_{a_1 \cdots a_m} \]
\[ \times \prod_{j=1}^M \text{Tr}_{[\tau_1]} \left[ \left\langle \exp \left[ F \zeta \sum_{\alpha=1}^n \tau_{j}^\alpha \right] \right\rangle_{\zeta} \right] \]
\[ \times \int \frac{dZ}{2\pi i} \exp \left[ Z^{\sum_{m=0}^n \sum_{(a_1 \cdots a_m)} \tilde{q}_{a_1 \cdots a_m} \tau^{a_1} \cdots \tau^{a_m}} \right] \right], \]

where \( T_m = e^{-n\beta \gamma} \cosh^n(\beta \gamma) \tanh^m(\beta \gamma) \). Comparing this expression with that obtained for the code of Sourlas in Eq. (A.7), one can see that the differences are the dimensionality \( M \) for Gallager codes instead of \( N \) for Sourlas (reflecting the fact that in the former the noise vector of dimension \( M \) is the dynamical variable) and the absence of disorder in the couplings, yielding a slightly modified definition for the constants \( T_m \).
4.4. Replica symmetric solution

The replica symmetric ansatz consists of assuming the following form for the order parameters:

\[ q_{\alpha_1 \cdots \alpha_m} = \int dx \, \pi(x) \, x^m \quad \hat{q}_{\alpha_1 \cdots \alpha_m} = \int d\hat{x} \, \hat{\pi}(\hat{x}) \, \hat{x}^m. \]  

(121)

By performing the limit \( \gamma \to \infty \), plugging (121) into (120), computing the normalization constant \( N' \), integrating in the complex variable \( Z \) and computing the trace (see Appendix B.2) we find:

\[
\langle Z^n \rangle_{A, \zeta} = \text{Extr}_{x, \hat{x}} \left\{ \exp \left[ -MC \left( \int dx \, d\hat{x} \, \pi(x) \, \hat{\pi}(\hat{x}) (1 + x \hat{x})^n - 1 \right) \right. \\
+ \left. \left( \frac{MC}{K} \int \prod_{j=1}^{K} dx_j \, \pi(x_j) \, (1 + \prod_{j=1}^{K} x_j)^n - 1 \right) \right] \\
\times \left( \int \prod_{j=1}^{C} d\hat{x}_j \, \hat{\pi}(\hat{x}_j) \left\langle \left[ \sum_{\sigma = \pm 1} e^{\sigma \beta F \hat{\zeta} \hat{\pi}(\hat{x})} \prod_{j=1}^{C} (1 + \sigma \hat{x}_j) \right]^n \right\rangle \right)^{M} \right\}. 
\]  

(122)

Using (115):

\[
f = \frac{1}{\beta} \text{Extr}_{x, \hat{x}} \left\{ \frac{C}{K} \ln 2 + C \int dx \, d\hat{x} \, \pi(x) \, \hat{\pi}(\hat{x}) \ln (1 + x \hat{x}) \right. \\
- \left. \frac{C}{K} \int \prod_{j=1}^{K} dx_j \, \pi(x_j) \ln (1 + \prod_{j=1}^{K} x_j) \right\}. 
\]  

(123)
\[ - \int \prod_{j=1}^{C} d\tilde{x}_j \, \hat{\pi}(\tilde{x}_j) \left\langle \ln \left[ \sum_{\sigma=\pm 1} \exp^{\sigma \beta F \zeta} \prod_{j=1}^{C} (1 + \sigma \tilde{x}_j) \right] \right\rangle_{\zeta} \].

The extremization above yields a pair of saddle-point equations:

\[
\hat{\pi}(\tilde{x}) = \int \prod_{j=1}^{K-1} dx_j \, \pi(x_j) \, \delta \left[ \tilde{x} - \prod_{j=1}^{K-1} x_j \right] \tag{124}
\]

\[
\pi(x) = \int \prod_{l=1}^{C-1} d\tilde{x}_l \, \tilde{\pi}(\tilde{x}_l) \left\langle \delta \left[ x - \tanh \left( \beta F \zeta + \sum_{l=1}^{C-1} \tanh \tilde{x}_l \right) \right] \right\rangle_{\zeta},
\]

where \( \beta = 1 \) (Nishimori temperature) and \( F = \frac{1}{2} \ln \left( \frac{1+\rho}{1-\rho} \right) \) for optimal decoding.

Following the derivation of Appendix A.3 very closely, the typical overlap \( \rho = \langle \frac{1}{N} \sum_{j=1}^{M} \zeta_j \hat{\tau}_j \rangle_{\zeta} \) between the estimate \( \hat{\tau}_j = \text{sgn}(\langle \tau_j \rangle_{\beta}) \) and the actual noise \( \zeta_j \) is given by:

\[
\rho = \int dh \, P(h) \, \text{sgn}(h) \tag{125}
\]

\[
P(h) = \int \prod_{l=1}^{C} d\tilde{x}_l \, \tilde{\pi}(\tilde{x}_l) \left\langle \delta \left[ h - \tanh \left( \beta F \zeta + \sum_{l=1}^{C} \tanh \tilde{x}_l \right) \right] \right\rangle_{\zeta}.
\]

4.5. Thermodynamic quantities and typical performance

The typical performance of a code as predicted by the replica symmetric theory can be assessed by solving (124) numerically and computing the overlap \( \rho \) using (125).
The numerical calculation can be done by representing distributions \( \pi \) and \( \hat{\pi} \) by histograms (we have used representations with 20000 bins), and performing Monte-Carlo integrations in an iterative fashion until a solution is found. Overlaps can be obtained by plugging the distribution \( \hat{\pi} \) that is a solution for (124) into (125).

Numerical calculations show the emergence of two solution types, the first corresponds to a totally aligned (ferromagnetic) state with \( \rho = 1 \) described by:

\[
\pi_{\text{ferro}}(x) = \delta[x - 1] \quad \hat{\pi}_{\text{ferro}}(\hat{x}) = \delta[\hat{x} - 1].
\]

The ferromagnetic solution is the only stable solution up to a specific noise level \( p_s \). Above \( p_s \), another stable solution with \( \rho < 1 \) (suboptimal ferromagnetic) can be obtained numerically. This solution is depicted in Fig.14 for \( K = 4 \), \( C = 3 \) and \( p = 0.20 \). The ferromagnetic state is always a stable solution for (124) and is present for all choices of noise level or construction parameters \( C \) and \( K \). The stability can be verified by introducing small perturbations to the solution and observing that the solution is recovered after a number of iterations of (124).

The free-energy for the ferromagnetic state at Nishimori's temperature is simply \( f_{\text{ferro}} = -F(1 - 2p) \). In Fig. 15 we show free-energies for \( K = 4 \) and \( R = 1/4 \), \( p_c \) indicates the noise level where coexistence between the ferromagnetic and suboptimal ferromagnetic phases occurs. This coexistence noise level coincides, within the numerical precision, with the information theoretic upper bound of Section 4.1. In Fig.16 we show pictorially how the replica symmetric free-energy landscape changes with the noise level \( p \).

In Fig.17 we show the overlap as a function of the noise level, as obtained for \( K = 4 \) and \( R = 1/4 \) (therefore \( C = 3 \)). Full lines indicate values corresponding to

\[\text{Figure 16. Pictorial representation of the replica symmetric free-energy landscape changing with the noise level } p. \text{ Up to } p_s \text{ there is only one stable state } F \text{ corresponding to the ferromagnetic state with } \rho = 1. \text{ At } p_s, \text{ a second stable suboptimal ferromagnetic state } F' \text{ emerges with } \rho < 1, \text{ as the noise level increases, coexistence is attained at } p_c. \text{ Above } p_c, F' \text{ becomes the global minimum dominating the system thermodynamics.}\]
states of minimum free-energy that are predicted thermodynamically. The general idea is that the macroscopic behaviour of the system is dominated by the global minimum of the free-energy (thermodynamic equilibrium state). After a sufficiently long time the system eventually visits configurations consistent with the minimum free-energy state staying there almost all of the time. The whole dynamics is ignored and only the stable equilibrium, in a thermodynamic sense, is taken into account. Also in Fig. 17 we show results obtained by simulating probability propagation decoding (black circles). The practical decoding stays in a meta-stable (in the thermodynamic sense) state between \( p_s \) and \( p_c \) and the practical maximum noise level corrected is actually given by \( p_s \).

Returning to the pictorial representation in Fig.16, the noise level \( p_s \) that provides the practical threshold is signalled by the appearance of spinodal points in the replica symmetric free-energy, defined as points separating (meta)stable and unstable regions in the space of thermodynamical configurations \((\rho)\). The noise level \( p_s \) may, therefore, be called spinodal noise level.

The solutions obtained must produce non-negative entropies to be physically meaningful. The entropy can be computed from the free-energy (123) as \( s = \beta \frac{\partial F}{\partial \beta} \) yielding:

\[
s = \beta (u(\beta) - f)
\]

\[
u(\beta) = - \int \prod_{j=1}^{C} d\hat{x}_j \hat{\rho}^* (\hat{x}_j) \left( \sum_{\tau=\pm 1} e^{\tau \beta F} \prod_{j=1}^{C} (1 + \tau \hat{x}_j) \left( \frac{\sum_{\tau=\pm 1} e^{\tau \beta F} \prod_{j=1}^{C} (1 + \tau \hat{x}_j)}{\sum_{\tau=\pm 1} e^{\tau \beta F} \prod_{j=1}^{C} (1 + \tau \hat{x}_j)} \right) \right)
\]

where \( \hat{\rho}^* \) is a solution for the saddle-point equations (124) and \( u(\beta) \) corresponds to

\[
\text{Figure 17. Overlaps for } K = 4, C = 3 \text{ and } R = 1/4. \text{ The full line corresponds to overlaps predicted by thermodynamical considerations. Up to } p_s \text{ only the ferromagnetic } \rho = 1 \text{ state is present, it then dominates the thermodynamics up to } p_c, \text{ where coexistence with suboptimal ferromagnetic states takes place. Dashed lines correspond to overlaps of non-dominant states.}
\]
the internal energy density at temperature $\beta$. For the ferromagnetic state $s_{\text{ferro}} = 0$ what indicates that the replica symmetric ferromagnetic solution is physical and that the number of micro-states consistent with the ferromagnetic state is at most of polynomial order in $N$. The entropy of the suboptimal ferromagnetic state can be obtained numerically. Up to the spinodal noise level $p_s$, the entropy vanishes as only the ferromagnetic state is stable. Above $p_s$, the entropy of the replica symmetric suboptimal ferromagnetic state is negative and, therefore, unphysical. At $p_c$, the entropy of the suboptimal ferromagnetic state becomes positive again. The internal energy density obtained numerically is depicted in Fig.18 being $u = -F(1 - 2p)$ for both ferromagnetic and suboptimal ferromagnetic states, justified by assuming Nishimori’s condition $\gamma \to \infty$, $\beta = 1$ and $F = \text{atanh}(1 - 2p)$ [Iba99] (see Appendix B.3).

The unphysical behavior of the suboptimal ferromagnetic solution between $p_s$ and $p_c$ indicates that the replica symmetric ansatz does not provide the correct physical description of the system. The construction of a complete one-step replica symmetry breaking theory turns out to be a difficult task in the family of models we focus on here [WS88, Mon98b, Mon98a]; although it may be possible in principle using a new method, recently introduced by Mezard and Parisi [MP01]. An alternative is to consider a frozen spins solution. In this case the entropy in the interval $p_s < p < p_c$ is corrected to $s_{\text{frozen}} = 0$ and the free-energy and internal energy are frozen to the values at $p_c$.

Any candidate to a physical description for the system would have to be compared with simulations to be validated. Nevertheless, our aim here is predicting the behavior of a particular decoding algorithm, namely, probability propagation. In the next section we will show that, to this end, the replica symmetric theory will be sufficient.
4.6. Codes on a cactus

In this section we present a statistical physics treatment of Gallager codes by employing a mean-field approximation based on the use of a generalized tree structure (Bethe lattice [WS87b]) known as Husimi cactus that is exactly solvable [Gu95, BL82, RK92, Gol91].

There are many different ways of building mean-field theories. One can make a perturbative expansion around a tractable model [Ple82, Tan00] or assume a tractable structure and variationally determine the model parameters [SJ98]. In the approximation we employ, the tractable structure is tree-like and the couplings $J_\mu$ are just assumed to be those of a model with cycles. In this framework the probability propagation decoding algorithm (PP) emerges naturally providing an alternative view to the relationship between PP decoding and mean-field approximations already observed in [KS98]. Moreover, this approach has the advantage of being slightly more controlled and easier to understand than replica calculations.

A Husimi cactus with connectivity $C$ is generated starting with a polygon of $K$ vertices with one Ising spin in each vertex (generation 0). All spins in a polygon interact through a single coupling $J_\mu$ and one of them is called the base spin. In Fig.19 we show the first step in the construction of a Husimi cactus, in a generic step the base spins of the $(C-1)(K-1)$ polygons in generation $n-1$ are attached to $K-1$ vertices of a polygon in the next generation $n$. This process is iterated until a maximum generation $n_{\text{max}}$ is reached, the graph is then completed by attaching $C$ uncorrelated branches of $n_{\text{max}}$ generations at their base spins. In this way each spin inside the graph is connected to $C$ polygons exactly. The local magnetization at the center $m_j$ can be obtained by fixing boundary (initial) conditions in the 0-th generation and iterating the related recursion equations until generation $n_{\text{max}}$ is reached. Carrying out the calculation in the thermodynamic limit corresponds to having $n_{\text{max}} \sim \ln M$ generations and $M \to \infty$.

The Hamiltonian of the model has the form (106) where $\mathcal{L}(\mu)$ denotes the polygon $\mu$ of the lattice. Due to the tree-like structure, local quantities far from the boundary can be calculated recursively by specifying boundary conditions. The typical decoding performance can therefore be computed exactly without resorting to replica calculations [Gu95].

We adopt the approach presented in [RK92] for obtaining recursion relations. The probability distribution $P_{\mu k}(\tau_k)$ for the base spin of the polygon $\mu$ is connected to
\((C - 1)(K - 1)\) distributions \(P_{ij}(\tau_j)\), with \(\nu \in \mathcal{M}(j) \setminus \mu\) (all polygons linked to \(j\) but \(\mu\)) of polygons in the previous generation:

\[
P_{ik}(\tau_k) = \frac{1}{N} \Tr(\tau_j) \exp \left[ \beta \gamma \left( J_{\mu} \tau_k \prod_{j \in \mathcal{L}(\mu) \setminus k} \tau_j - 1 \right) + \beta F \tau_k \right] \prod_{\nu \in \mathcal{M}(j) \setminus \mu} \prod_{j \in \mathcal{L}(\mu) \setminus k} P_{ij}(\tau_j),
\]

where the trace is over the spins \(\tau_j\) such that \(j \in \mathcal{L}(\mu) \setminus k\).

The effective field \(\hat{x}_{\nu j}\) on a base spin \(j\) due to neighbors in polygon \(\nu\) can be written as:

\[
e^{-2\hat{x}_{\nu j}} = e^{2\beta \mu \frac{P_{\nu j}(-)}{P_{\nu j}(+)}}.
\]

Combining (128) and (129) we find the recursion relation (see Appendix B.4 for details):

\[
e^{-2\hat{x}_{\mu k}} = \frac{\Tr(\tau_j) e^{-\beta J_{\mu} \prod_{\nu \in \mathcal{M}(j) \setminus \mu} \tau_j + \sum_{j \in \mathcal{L}(\mu) \setminus k} (\beta F + \sum_{\nu \in \mathcal{M}(j) \setminus \mu} \hat{x}_{\nu j}) \tau_j}}{\Tr(\tau_j) e^{\beta J_{\mu} \prod_{\nu \in \mathcal{M}(j) \setminus \mu} \tau_j + \sum_{j \in \mathcal{L}(\mu) \setminus k} (\beta F + \sum_{\nu \in \mathcal{M}(j) \setminus \mu} \hat{x}_{\nu j}) \tau_j}}.
\]

By computing the traces and taking \(\gamma \to \infty\) and \(\beta = 1\) one obtains:

\[
\hat{x}_{\mu k} = \tanh \left( J_{\mu} \prod_{j \in \mathcal{L}(\mu) \setminus k} \tanh(F + \sum_{\nu \in \mathcal{M}(j) \setminus \mu} \hat{x}_{\nu j}) \right).
\]

The effective local magnetization due to interactions with the nearest neighbors in one branch is given by \(\hat{m}_{\mu j} = \tanh(\hat{x}_{\mu j})\). The effective local field on a base spin \(j\) of a polygon \(\mu\) due to \(C - 1\) branches in the previous generation and due to the external field is \(x_{\mu j} = F + \sum_{\nu \in \mathcal{M}(j) \setminus \mu} \hat{x}_{\nu j}\); the effective local magnetization is therefore \(m_{\mu j} = \tanh(x_{\mu j})\). Equation (131) can then be rewritten in terms of \(\hat{m}_{\mu j}\) and \(m_{\mu j}\) and the PP equations [Mac99, KS98, KF98] can be recovered:

\[
m_{\mu k} = \tanh \left( F + \sum_{\nu \in \mathcal{M}(k) \setminus \mu} \tanh(\hat{m}_{\nu k}) \right)
\]

\[
\hat{m}_{\mu k} = \prod_{j \in \mathcal{L}(\mu) \setminus k} m_{\mu j}.
\]

Once the magnetization on the boundary (0-th generation) are assigned, the local magnetization \(m_j\) in the central site is determined by iterating (132) and computing:

\[
m_j = \tanh \left( F + \sum_{\nu \in \mathcal{M}(j)} \tanh(\hat{m}_{\nu j}) \right).
\]

A free-energy can be obtained by integration of (132) [MKSV00, VSK00b, BL82]. The equations (132) describing PP decoding represent extrema of the following free-energy:

\[
\mathcal{F}(\{m_{\mu k}, \hat{m}_{\mu k}\}) = \sum_{\mu = 1}^{M-N} \sum_{i \in \mathcal{L}(\mu)} \ln(1 + m_{\mu i} \hat{m}_{\mu i}).
\]
Figure 20. Transitions for Gallager codes with $K = 6$ (left) and $K = 10$ (right). Shannon’s bound (dashed line), information theory upper bound (full line) and thermodynamic transition obtained numerically (o). Transitions obtained by Monte Carlo integration of Eq.(138) ($\xi$) and by simulations of PP decoding ($+$, $M = 5000$ averaged over 20 runs) are also shown. Black squares are estimates for practical thresholds based on Sec.4.8. In both figures, symbols are chosen larger than the error bars.

\[
- \sum_{\mu=1}^{M-N} \ln(1 + J_{\mu} \prod_{i \in \mathcal{L}(\mu)} m_{\mu i}) \\
- \sum_{j=1}^{M} \ln \left( e^F \prod_{\mu \in \mathcal{M}(j)} (1 + \hat{m}_{\mu j}) + e^{-F} \prod_{\mu \in \mathcal{M}(j)} (1 - \hat{m}_{\mu j}) \right)
\]

The iteration of the maps (132) is actually one out of many different methods of finding stable extrema of this free-energy.

The decoding process can be performed by iterating the multidimensional map (132) using some defined scheduling. Assume that the iterations are performed in parallel using the following procedure:

(i) Effective local magnetizations are initialized as $m_{\mu k} = 1 - 2p$, reflecting prior probabilities.

(ii) Conjugate magnetizations $\hat{m}_{\mu k}$ are updated.

(iii) Magnetizations $m_{\mu k}$ are computed.

(iv) If convergence or a maximal number of iterations is attained, stop. Otherwise go to step (ii).

Equations (132) have fixed points that are inconveniently dependent on the particular noise vector $\zeta$. By applying the gauge transformation $J_{\mu} \rightarrow 1$ and $\tau_j \rightarrow \tau_j \zeta_j$ we get a map with noise independent fixed points that has the following form:

\[
m_{\mu k} = \tanh \left( \zeta_k F + \sum_{\nu \in \mathcal{M}(k) \setminus \mu} \text{atanh} \left( \hat{m}_{\nu k} \right) \right)
\]
\[ \hat{\mathcal{m}}_{\mu k} = \prod_{j \in \mathcal{L}(\mu)/k} m_{\mu j}. \]  

(136)

In terms of effective fields \( x_{\mu k} \) and \( \hat{x}_{\mu k} \) we have:

\[ x_{\mu k} = \zeta_k F + \sum_{\nu \in M(k) \setminus \mu} \hat{x}_{\nu k} \quad \hat{x}_{\mu k} = \text{atanh} \left( \prod_{j \in \mathcal{L}(\mu)/k} \tanh(x_{\mu j}) \right). \]  

(137)

The above equations provide a microscopic description for the dynamics of a probability propagation decoder, a macroscopic description can be constructed by retaining only statistical information about the system, namely by describing the evolution of histograms of variables \( x_{\mu k} \) and \( \hat{x}_{\mu k} \).

Assume that the effective fields \( x_{\mu k} \) and \( \hat{x}_{\mu k} \) are random variables independently sampled from the distributions \( P(x) \) and \( \hat{P}(\hat{x}) \) respectively, in the same way assume that \( \zeta_j \) is sampled from \( P(\zeta) = (1 - p) \delta(\zeta - 1) + \delta(\zeta + 1) \). A recursion relation in the space of probability distributions \([BL82]\) can be found from Eq. (137):

\[ P_n(x) = \int d\zeta P(\zeta) \prod_{l=1}^{C-1} d\hat{x}_l \hat{P}_{n-1}(\hat{x}_l) \delta \left[ x - F\zeta - \sum_{l=1}^{C-1} \hat{x}_l \right] \]

\[ \hat{P}_{n-1}(\hat{x}) = \int dx_j P_{n-1}(x_j) \delta \left[ \hat{x} - \text{atanh} \left( \prod_{j=1}^{K-1} \tanh(x_j) \right) \right], \]  

(138)

where \( P_n(x) \) is the distribution of effective fields at the \( n \)-th generation due to the previous generations and external fields, in the thermodynamic limit the distribution far from the boundary will be \( P_\infty(x) \) (generation \( n \to \infty \)). The local field distribution

\[ F = \frac{1}{\lambda} \sum_{\mu \in \mathcal{L}(\mu)} m_{\mu \mu} \log \left( \frac{1}{z_{\mu \mu}} \right) \]

\[ \lambda = \sum_{\mu \in \mathcal{L}(\mu)} m_{\mu \mu} \]

\[ z_{\mu \mu} = \sum_{\nu \in \mathcal{L}(\mu) \setminus \mu} \sum_{\zeta \in \mathcal{L}(\nu)} P(\zeta) \delta(\zeta - 1) \]
Figure 22. PP decoding convergence time as a function of the code size $(M - N)$ for $K = 4$, $C = 3$ and $p = 0.05$, therefore, well below the threshold. The convergence time clearly does not scale with the system size.

at the central site is computed by replacing $C - 1$ by $C$ in the first equation (138), taking into account $C$ polygons in the generation just before the central site, and inserting the distribution $P_\infty(x)$:

$$P(h) = \int d\zeta \, P(\zeta) \, \prod_{l=1}^C d\tilde{x}_l \, E_\infty(\tilde{x}_l) \, \delta \left[ x - F\zeta - \sum_{l=1}^C \tilde{x}_l \right]. \quad (139)$$

Equations (138) are identical to equations (124) obtained by the replica symmetric theory [KMS00, MKSV00, VSK00b] if the variables describing fields are transformed to those of local magnetizations through $x \rightarrow \tanh(\beta x)$.

In Fig.14 we show empirical histograms obtained by performing 100 runs of PP decoding for 10 different codes of size $M = 5000$ and compare with a distribution obtained by solving equations like (138). The practical PP decoding is performed by setting initial conditions as $m_{ij} = 1 - 2p$ to correspond to the prior probabilities and iterating (132) until stationarity or a maximum number of iterations is attained [Mac99]. The estimate for the noise vector is then produced by computing $\tilde{\gamma}_j = \text{sign}(m_j)$. At each decoding step the system can be described by histograms of variables (132), this is equivalent to iterating (138) (a similar idea was presented in [Mac99, Dav98]).

In Fig.20 we summarize the transitions obtained for $K = 6$ and $K = 10$. A dashed line indicates Shannon’s limit, the full line represents the information theoretic upper bound of Section 4.1, white circles stand for the coexistence line obtained numerically. Diamonds represent spinodal noise levels obtained by solving (138) numerically and (+) are results obtained by performing 20 runs using PP decoding. It is interesting to observe that the practical performance tends to get worse as $K$ grows large, what agrees with the general belief that decoding gets harder as Shannon’s limit is approached.
Figure 23. Tanner graph representing the neighborhood of a bit node in an irregular Gallager code. Black circles represent checks and white circles represent bits.

4.7. Tree-like approximation and the thermodynamic limit

The geometrical structure of a Gallager code defined by the matrix $A$ can be represented by a bipartite graph as in Fig.23 (Tanner graph) [KF98] with bit and check nodes (in this case, we show an irregular construction where the values of $K$ and $C$ are not fixed). Each column $j$ of $A$ represents a bit node and each row $\mu$ represents a check node, $A_{\mu j} = 1$ means that there is an edge linking bit $j$ to check $\mu$. It is possible to show [RU01] that for a random ensemble of regular codes, the probability of completing a cycle after walking $l$ edges starting from an arbitrary node is upper bounded by $P[l; K, C, M] \leq \ell^2 K^d / M$. It implies that for very large $M$ only cycles of at least order $\ln M$ survive. In the thermodynamic limit $M \to \infty$ and the probability $P[l; K, C, M] \to 0$ for any finite $l$ and the bulk of the system is effectively tree-like. By mapping each check node to a polygon with $K$ bit nodes as vertices, one can map a Tanner graph into a Husimi lattice that is effectively a tree for any number of generations of order less than $\ln M$. In Fig.22 we show that the number of iterations of (132) required for convergence far from the threshold does not scale with the system size, therefore, it is expected that the interior of a tree-like lattice approximates a Gallager code with increasing accuracy as the system size increases. Figure 21 shows that the approximation is fairly good even for sizes as small as $M = 100$ when compared to theoretical results and simulations for size $M = 5000$. Nevertheless, the difference increases as the spinodal noise level approaches, what seems to indicate the breakdown of the approximation. A possible explanation is that convergence times larger than $O(\ln M)$ may be required in this region. An interesting analysis of the convergence properties of probability propagation algorithms for some specific graphical models can be found in [Wei97].
4.8. Estimating spinodal noise levels

We now estimate the threshold noise level $p_s$ by introducing a measure for the number of parity-checks violated by a bit $\tau_l$:

$$E_l = - \sum_{\mu \in M(l)} \left( J_{\mu l} \prod_{j \in L(\mu) \setminus l} \tau_j - 1 \right). \tag{140}$$

By using gauged variables:

$$E_l = - \sum_{\mu \in M(l)} \left( \eta \prod_{j \in L(\mu) \setminus l} \tau_j - 1 \right). \tag{141}$$

Suppose that random guesses are generated by sampling the prior distribution, their typical overlap will be $\rho = 1 - 2p$. Assume now that the vectors sampled are corrected by flipping $\tau_l$ if $E_l = C$. If the landscape has a single dominant minimum we expect that this procedure will tend to increase the overlap $\rho$ between $\tau$ and the actual noise vector $\zeta$ in the first step up to the noise level $p_s$, where suboptimal microscopic configurations are expected to emerge. Above $p_s$ there is a large number of suboptimal ferromagnetic micro-states with an overlap around $\rho = 1 - 2p$ (see Fig.21), and we expect that if a single bit of a randomly guessed vector is corrected, the overlap will then either increase or decrease, staying unchanged on average. A vanishing variation in the mean overlap would, therefore, signal the emergence of suboptimal micro-states at $p_s$.

The probability that a bit $\tau_l = +1$ is corrected is:

$$P(E_l = C \mid \tau_l = +1) = \prod_{\mu \in M(l)} P \left\{ \prod_{j \in L(\mu) \setminus l} \tau_j = -1 \right\}. \tag{142}$$

For $\tau_l = -1$:

$$P(E_l = C \mid \tau_l = -1) = \prod_{\mu \in M(l)} \left[ 1 - P \left\{ \prod_{j \in L(\mu) \setminus l} \tau_j = -1 \right\} \right]. \tag{143}$$

Considering vectors sampled from a prior $P(\tau) = (1 - p) \delta(\tau - 1) + p \delta(\tau + 1)$ we have:

$$P \left\{ \prod_{j \in L(\mu) \setminus l} \tau_j = -1 \right\} = \frac{1}{2} - \frac{1}{2} (1 - 2p)^{K-1}. \tag{144}$$

The gauged overlap is defined as $\rho = \sum_{j=1}^{M} S_j$ and the variation on the overlap after flipping a bit $l$ is $\Delta \rho = \rho_l - \rho_0 = S_l^1 - S_l^0$. The mean variation in the overlap due to a flip in a bit $\tau_l$ with $E_l = C$ is therefore:

$$\frac{1}{2} \langle \Delta \rho \rangle = P(\tau_l = +1 \mid E_l = C) - P(\tau_l = -1 \mid E_l = C) \tag{145}$$

$$= \frac{\sum_{\tau_l = \pm 1} \eta P(E_l = C \mid \tau_l) P(\tau_l)}{\sum_{\tau_l = \pm 1} P(E_l = C \mid \tau_l) P(\tau_l)},$$
where we applied the Bayes theorem to obtain the last line.

By plugging the prior probability, (142) and (144) into the above expression we get:

\[
\frac{1}{2} \langle \Delta \rho \rangle = \frac{[1 - (1 - 2p)^{K-1}]^C (1 - p) - [1 + (1 - 2p)^{K-1}]^C p}{[1 - (1 - 2p)^{K-1}]^C (1 - p) + [1 + (1 - 2p)^{K-1}]^C p}.
\] (146)

At \( p_s \) we have \( \langle \Delta \rho \rangle = 0 \) and:

\[
\frac{p_s}{1 - p_s} = \frac{[1 - (1 - 2p_s)^{K-1}]}{[1 + (1 - 2p_s)^{K-1}]}.
\] (147)

The above equation can be solved numerically yielding reasonably accurate estimates for practical thresholds \( p_s \) as can be seen in Fig.20.

MacKay [Mac99] and Gallager [Gal62, Gal63] introduced probabilistic decoding algorithms whose performance analysis is essentially the same those as presented here. However, the results obtained in Section 4.3 put the analysis into a broader perspective: algorithms that generate decoding solutions in polynomial time, as is the case of probabilistic decoding or probability propagation, seem to be bounded by the practical threshold \( p_s \) due to the presence of suboptimal solutions. On other hand, decoding in exponential time is always possible up to the thermodynamic transition at \( p_c \) (with \( p_c \) attaining channel capacity if \( K \to \infty \)), by performing an exhaustive search for the global minimum of the free-energy (134).

5. MacKay-Neal Codes

MacKay-Neal (MN) codes were introduced in [MN95] as a variation on Gallager codes. As in the case of Gallager codes (see Section 4), MN codes are defined by two very sparse matrices, but with the difference that information on both noise and signal is incorporated to the syndrome vector. MN codes are also decoded using sparse matrices while encoding uses a dense matrix, what yields good distance properties and a decoding problem solvable in linear time by using the methods of probability propagation.

Cascading codes, a class of constructions inside the MN family recently proposed by Kanter and Saad [KS99b, KS00b, KS00a], have been shown to outperform some of the cutting-edge Gallager and turbo code constructions. We will discuss cascading codes in the next section, but this fact alone justifies a thorough study of MN codes.

Theorems showing the asymptotic goodness of the MN family have been proved in [Mac99]. By assuming that equal message and noise biases (for a BSC), it was proved that the probability of error vanishes as the message length increases and that it is possible to get as close as desired to channel capacity by increasing the number of non-zero elements in a column of the very sparse matrices defining the code.

It can also be shown by a simple upper bound that MN codes, unlike Gallager codes, might as well attain Shannon’s bound for a finite number of non-zero elements in the columns of the very sparse matrices, given that unbiased messages are used. This upper bound does not guarantee that channel capacity can be attained in polynomial time or even that it can be attained at all. Results obtained using statistical physics techniques
[KMS00, MKSV00, VSK00b, VSK00a] seem to indicate that Shannon’s bound can actually be approached with exponential time decoding. This feature is considered to be new and somewhat surprising [Mac00b].

Statistical physics has been applied to analyze MN codes and its variants in [KMS00, MKSV00, VSK00b]. In the analysis we use the replica symmetric theory to obtain all relevant thermodynamic quantities and to calculate the phase diagram. The theory also yields a noise level where suboptimal solutions emerge that is in connection with the practical thresholds observed when probability propagation decoding is used.

Assuming that a message is represented by a binary vector $\xi \in \{0, 1\}^N$ sampled independently from the distribution $P(\xi) = (1 - p) \delta(\xi) + p \delta(\xi - 1)$, the MN encoding process consists of producing a binary vector $t \in \{0, 1\}^M$ defined by

$$t = G\xi \pmod{2},$$

where all operations are performed in the field $\{0, 1\}$ and are indicated by $(\pmod{2})$. The code rate is, therefore, $R = N/M$.

The generator matrix $G$ is an $M \times N$ dense matrix defined by

$$G = C_n^{-1}C_s \pmod{2},$$

with $C_n$ being an $M \times M$ binary invertible sparse matrix and $C_s$ an $M \times N$ binary sparse matrix.

The transmitted vector $t$ is then corrupted by noise. We here assume a memoryless binary symmetric channel (BSC), namely, noise is represented by a binary vector $\zeta \in \{0, 1\}^M$ with components independently drawn from the distribution $P(\zeta) = (1 - p) \delta(\zeta) + p \delta(\zeta - 1)$.

The received vector takes the form

$$r = G\xi + \zeta \pmod{2}.$$  \hfill (150)

Decoding is performed by pre-processing the received message with the matrix $C_n$ and producing the syndrome vector

$$z = C_n r = C_s \xi + C_n \zeta \pmod{2},$$

from which an estimate $\hat{\xi}$ for the message can be directly obtained.

An MN code is called regular if the number of elements set to one in each row of $C_s$ is chosen to be $K$ and the number of elements in each column is set to be $C$. For the square matrix $C_n$ the number of elements in each row (or column) is set to $L$. In this case the total number of ones in the matrix $C_s$ is $MK = NC$, yielding that the rate can alternatively be expressed as $R = K/C$.

In contrast, an MN code is called irregular if each row $m$ in $C_s$ and $C_n$ contains $K_m$ and $L_m$ non-zero elements respectively. In the same way, each column $j$ of $C_s$ contains $C_j$ non-zero elements and each column $l$ of $C_n$ contains $D_l$ non-zero elements.

Counting the number of non-zero elements in the matrices leads to the following relations:

$$\sum_{j=1}^{N} C_j = \sum_{\mu=1}^{M} K_\mu \quad \sum_{l=1}^{M} D_l = \sum_{\mu=1}^{M} L_\mu,$$  \hfill (152)
The code rate is, therefore, \( R = \frac{K}{C} \), where:

\[
K = \frac{1}{M} \sum_{\mu=1}^{M} K_{\mu} \quad \quad C = \frac{1}{N} \sum_{j=1}^{N} C_{j}.
\]

(153)

The Bayes optimal estimator \( \hat{\xi} \) for the message \( \xi \) is \( \hat{\xi}_{j} = \arg\max_{S_{j}} P(S_{j} \mid z) \). The performance of this estimator is measured by the probability of bit error \( p_{b} = 1 - 1/N \sum_{j=1}^{N} \delta[\hat{\xi}_{j}; \xi_{j}] \), where \( \delta[\cdot] \) is the Kronecker delta. Knowing the matrices \( C_{s} \) and \( C_{n} \), the syndrome vector \( z \), the noise level \( p \) and the message bias \( p_{\xi} \); the posterior probability is computed by applying Bayes theorem:

\[
P(S, \tau \mid z) = \frac{1}{Z} \chi[z = C_{s}S + C_{n}\tau \pmod{2}] P(S)P(\tau),
\]

(154)

where \( \chi[X] \) is an indicator function providing 1 if \( X \) is true and 0 otherwise.

To obtain the estimate one has to compute the marginal posterior

\[
P(S_{j} \mid z) = \sum_{\{S_{i} \neq \hat{S}_{j}\}} \sum_{\tau} P(S, \tau \mid z),
\]

(155)

which requires \( O(2^{N}) \) operations and is impractical for long messages. Again we can use the sparseness of \( [C_{s} \mid C_{n}] \) and the methods of probability propagation for decoding, what requires only \( O(N) \) operations.

When \( p = p_{\xi} \), MN and Gallager codes are equivalent under a proper transformation of parameters, as the code rate is \( R = N/M \) for MN codes and \( R = 1 - N/M \) for Gallager codes. The main difference between the codes is in the syndrome vector \( z \). For MN codes the syndrome vector incorporates information on both message and noise while for Gallager codes only information on the noise is present (see Eq.(103)). This feature opens the possibility of adjusting the code behavior by controlling the message bias \( p_{\xi} \).

An MN code can be thought as a non-linear code [Mac00c]. Redundancy in the original message could be removed (introduced) by using a source (de)compressor defined by some non-linear function \( \xi = g(\xi_{0}; p_{\xi}) \) and encoding would then be \( t = Gg(\xi_{0}; p_{\xi}) \pmod{2} \). In the following we show that other new features emerge due to the introduction of the parameter \( p_{\xi} \).

5.1. Upper bound on achievable rates

In a regular MN code the syndrome vector \( z = C_{s}S + C_{n}\tau \pmod{2} \) is a sum of \( K \) message bits drawn from the distribution \( P(\xi) = (1 - p_{\xi}) \delta(\xi) + p_{\xi} \delta(\xi - 1) \) and \( L \) noise bits drawn from \( P(\zeta) = (1 - p) \delta(\zeta) + p \delta(\zeta - 1) \).

The probability of \( z_{j} = 1 \) is (see Appendix C.1)

\[
p_{z_{j}}(K, L) = \frac{1}{2} - \frac{1}{2}(1 - 2p_{\xi})^{K}(1 - 2p)^{L}.
\]

(156)

The maximum information content in the syndrome vector is \( MH_{2}(p_{z_{j}}(K, L)) \) (in bits or shannons), where \( H_{2}(x) \) is the binary entropy. The amount of information needed to
reconstruct both the message vector $\mathbf{e}$ and the noise vector $\mathbf{z}$ is $NH_2(p_{\xi}) + MH_2(p)$ (in bits or shannons). Thus, it is a necessary condition for successful decoding that:

\[
M H_2(p_{\xi}(K, L)) \geq N H_2(p_{\xi}) + M H_2(p)
\]

\[
H_2(p_{\xi}(K, L)) - H_2(p) \geq R H_2(p_{\xi})
\]

\[
R \leq \frac{H_2(p_{\xi}(K, L)) - H_2(p)}{H_2(p_{\xi})}.
\]

(157)

For the case $p_{\xi} = p$ and $L = C$, we can recover bounds (105) for Gallager codes with dimensions and parameters redefined as $M' = M + N$, $N' = N$ and $K' = K + L$. In [Mac99], a theorem stating that channel capacity can be attained when $K \to \infty$ was proved for this particular case.

If unbiased $(p_{\xi} = 1/2)$ messages are used, $H_2(p_{\xi}) = 1$, $H_2(p_{\xi}(K, L)) = 1$ and the bound (157) becomes

\[
R \leq 1 - H_2(p),
\]

(158)
i.e., MN codes may be capable of attaining channel capacity even for finite $K$ and $L$, given that unbiased messages are used.

5.2. Statistical physics formulation

The statistical physics formulation for MN codes is a straightforward extension of the formulation presented for Gallager codes. The field $\{\{\{0, 1\}, + (\text{mod } 2)\}$ is replaced by $\{\{\pm 1\}, \times\}$ [Sou89] and the syndrome vector acquires the form:

\[
\mathcal{J}_\mu = \prod_{j \in L_\mu} e_j \prod_{l \in \mathcal{L}_n(\mu)} \zeta
\]

(159)

where $j = 1, \cdots, N$, $l = 1, \cdots, M$ and $\mu = 1, \cdots, M$.

The $K_\mu$ indices of nonzero elements in the row $\mu$ of the signal matrix $\mathbf{C}_s$ are given by $L_\mu(\mu) = \{j_1, \cdots, j_{K_\mu}\}$, and in a column $j$ are given by $\mathcal{M}_s(j) = \{\mu_1, \cdots, \mu_{C_j}\}$. In the same way, for the noise matrix $\mathbf{C}_n$, the $L_\mu$ indices of nonzero elements in the row $\mu$ are given by $L_n(\mu) = \{j_1, \cdots, j_{N_\mu}\}$, and in a column $l$ are given by $\mathcal{M}_n(l) = \{\mu_1, \cdots, \mu_{D_l}\}$.

Under the assumption that priors $P(\mathbf{S})$ and $P(\mathbf{T})$ are completely factorizable, the posterior (154) corresponds to the limit $\gamma \to \infty$ and $\beta = 1$ (Nishimori temperature) if:

\[
P_\gamma(\mathbf{S}, \mathbf{T} \mid \mathcal{J}) = \frac{1}{Z} \exp [-\beta \mathcal{H}_\gamma(\mathbf{S}, \mathbf{T}; \mathcal{J})]
\]

(160)

\[
\mathcal{H}_\gamma(\mathbf{S}, \mathbf{T}; \mathcal{J}) = - \gamma \sum_{\mu=1}^{M} \left( \mathcal{J}_\mu \prod_{j \in L_\mu(\mu)} S_j \prod_{l \in \mathcal{L}_n(\mu)} \tau_l - 1 \right)
\]

\[
- F_s \sum_{j=1}^{N} S_j - F_n \sum_{l=1}^{M} \tau_l,
\]

with $F_s = \frac{1}{\beta} \tanh \left( \frac{1}{\beta} p_{\xi_s} \right)$ and $F_n = \frac{1}{\beta} \tanh \left( \frac{1}{\beta} p_{\xi_n} \right)$ (Nishimori condition [Iba99]).

By applying the gauge transformation $S_j \mapsto S_j e_j$ and $\tau_l \mapsto \tau_l \zeta$ the couplings can be gauged out $\mathcal{J}_\mu \mapsto 1$, eliminating the disorder. The model is free of frustration (as
in [Tou77], the model is flat. Similarly to Gallager codes, the resulting Hamiltonian consists of two sub-lattices interacting via multi-spin ferromagnetic iterations with finite connectivity in random fields $\xi_j F_s$ and $\zeta F_n$:

\[
\mathcal{H}_{\gamma}^{\text{gauge}}(\mathbf{S}, \tau; \xi, \zeta) = -\gamma \sum_{\mu=1}^{M} \left( \prod_{j \in \mathcal{L}_\mu} S_j \prod_{l \in \mathcal{L}_\mu} \tau_l \right) - F_s \sum_{j=1}^{N} \xi_j S_j - F_n \sum_{l=1}^{M} \zeta \tau_l. 
\] (161)

At the Nishimori condition $\gamma \to \infty$, and the model can also be regarded as a paramagnet with restricted configuration space on a non-uniform external field:

\[
\mathcal{H}_{\gamma}^{\text{gauge}}((\mathbf{S}, \tau) \in \Omega; \xi, \zeta) = -F_s \sum_{j=1}^{N} \xi_j S_j - F_n \sum_{l=1}^{M} \zeta \tau_l, 
\] (162)

where

\[
\Omega = \{ (\mathbf{S}, \tau) : \prod_{j \in \mathcal{L}_\mu} S_j \prod_{l \in \mathcal{L}_\mu} \tau_l = 1, \mu = 1, \cdots, M \}. 
\] (163)

Optimal decoding consists of finding local magnetizations at the Nishimori temperature in the signal sub-lattice $m_j = \langle S_j \rangle_{\beta_N}$ and calculating Bayesian estimates $\hat{\xi}_j = \text{sgn}(m_j)$.

The probability of bit error is

\[
p_b = \frac{1}{2} - \frac{1}{2N} \sum_{j=1}^{N} \xi_j \text{sgn}(m_j), 
\] (164)

connecting the code performance with the computation of local magnetizations.

5.3. Replica theory

The replica theory for MN codes is the theory constructed for Gallager codes, with the introduction of extra dynamical variables $\mathbf{S}$. The gauged Hamiltonian (161) is written as:

\[
\mathcal{H}_{\gamma}^{\text{gauge}}(\mathbf{S}, \tau; \xi, \zeta) = -\gamma \sum_{\langle j \ell \rangle} \mathcal{A}_{j\ell} (S_{j_1} \cdots S_{j_K} \tau_{\ell_1} \cdots \tau_{\ell_L} - 1) - F_s \sum_{j=1}^{N} \xi_j S_j - F_n \sum_{l=1}^{M} \zeta \tau_l, 
\] (165)

where $\langle j \ell \rangle$ is a shorthand for $\langle j_1 \cdots j_K \ell_1 \cdots \ell_L \rangle$.

Code constructions are described by the tensor $\mathcal{A}_{j\ell} \in \{0, 1\}$ that specifies a set of indices $\langle j_1 \cdots j_K \ell_1 \cdots \ell_L \rangle$ corresponding to non-zero elements in a particular row of the matrix $[C_n | C_n]$. To cope with non-invertible $C_n$ matrices we can start by considering an ensemble with uniformly generated $M \times M$ matrices. The non-invertible matrices can be made invertible by eliminating a $\epsilon \sim O(1)$ number of rows and columns, resulting
in an ensemble of \((M - \epsilon) \times (M - \epsilon)\) invertible \(C_n\) matrices and \((M - \epsilon) \times (N - \epsilon)\) \(C_s\) matrices. As we are interested in the thermodynamic limit we can neglect \(O(1)\) differences and compute the averages in the original space of \(M \times M\) matrices. The averages are then performed over an ensemble of codes generated as follows:

(i) Sets of numbers \(\{C_j\}_{j=1}^N\) and \(\{D_l\}_{l=1}^M\) are sampled independently from distributions \(P_C\) and \(P_D\) respectively;
(ii) Tensors \(A_{jl}\) are generated such that

\[
\sum_{jl} A_{jl} = M,
\]

\[
\sum_{(j_1 \cdots j_K l_1 \cdots l_L = 1 \cdots L)} A_{jl} = C_j \quad \sum_{(j_1 \cdots j_K l_1 = 1 \cdots L)} A_{jl} = D_l.
\]

The free-energy is computed by the replica method as:

\[
f = -\frac{1}{\beta} \lim_{N \to \infty} \frac{1}{N} \frac{\partial}{\partial n} \left. \langle Z^n \rangle_{\xi, \zeta} \right|_{n=0}
\]

(166)

The replicated partition function is:

\[
\langle Z^n \rangle_{\xi, \zeta} = \sum_{S_1, \ldots, S_n} \sum_{\tau_1, \ldots, \tau_n} \prod_{j=1}^N \left\langle \exp \left( F_s \xi \beta \sum_{\alpha=1}^n S_j^\alpha \right) \right\rangle \xi
\]

\[
\times \left( \prod_{l=1}^M \left\langle \exp \left( F_n \zeta \beta \sum_{\alpha=1}^n \tau_l^\alpha \right) \right\rangle \zeta \right)
\]

\[
\times \left\langle \prod_{j_l} \prod_{\alpha=1}^n \exp \left[ \beta \gamma A_{jl} (S_{j_1}^\alpha \cdots S_{j_K}^\alpha \tau_{l_1}^\alpha \cdots \tau_{l_L}^\alpha - 1) \right] \right\rangle_A.
\]

(167)

The average over constructions \(\langle \cdots \rangle_A\) is:

\[
\langle \cdots \rangle_A = \sum_{\{C_j, D_l\}} \prod_{j=1}^N P_C(C_j) \prod_{l=1}^M P_D(D_l) \frac{1}{N} \delta \left( \sum_{(j_1 \cdots j_K l_1 \cdots l_L)} A_{jl} - C_j \right)
\]

\[
\times \delta \left( \sum_{(j_1 = l_1 \cdots l_K)} A_{jl} - D_l \right) (\cdots)
\]

\[
= \sum_{\{C_j, D_l\}} \prod_{j=1}^N P_C(C_j) \prod_{l=1}^M P_D(D_l)
\]

\[
\times \frac{1}{N} \sum_{\{A\}} \prod_{j=1}^N \left[ \int \frac{dZ_j}{2\pi i} \frac{1}{Z_j^{-1}} \frac{Z_j^{-1}}{Z_j^{1+1}} \frac{\sum_{(j_1 \cdots j_K l_1 \cdots l_L)} A_{jl}}{Z_j^{(j_1 \cdots j_K l_1 \cdots l_L)}} \right]
\]

\[
\times \prod_{l=1}^M \left[ \int \frac{dY_l}{2\pi i} \frac{1}{Y_l Y_l^{-1}} \frac{\sum_{(j_1 \cdots j_K l_1 \cdots l_L)} A_{jl}}{Y_l^{(j_1 \cdots j_K l_1 \cdots l_L)}} \right] (\cdots),
\]

(168)
where the first sum is over profiles \( \{C_j, D_l\} \) composed by \( N \) numbers drawn independently from \( P_C(C) \) and \( M \) numbers drawn from \( P_D(D) \). The second sum is over constructions \( A \) consistent with the profile \( \{C_j, D_l\} \).

The signal average \( \langle \cdots \rangle_\xi \) has the form:

\[
\langle \cdots \rangle_\xi = \sum_{\xi = -1,+1} (1 - p_\xi) \delta(\xi - 1) + p_\xi \delta(\xi + 1) (\cdots). \tag{169}
\]

Similarly, the noise average \( \langle \cdots \rangle_\zeta \) is:

\[
\langle \cdots \rangle_\zeta = \sum_{\zeta = -1,+1} (1 - p) \delta(\zeta - 1) + p \delta(\zeta + 1) (\cdots). \tag{170}
\]

Along the same steps described for Gallager codes, we compute averages above and introduce auxiliary variables via

\[
\int dq_{\alpha_1 \cdots \alpha_m} \delta \left( q_{\alpha_1 \cdots \alpha_m} - \frac{1}{N} \sum_i^N Z_i S_i^{\alpha_1} \cdots S_i^{\alpha_m} \right) = 1 \tag{171}
\]

\[
\int dr_{\alpha_1 \cdots \alpha_m} \delta \left( r_{\alpha_1 \cdots \alpha_m} - \frac{1}{M} \sum_i^M Y_i \tau_i^{\alpha_1} \cdots \tau_i^{\alpha_m} \right) = 1 \tag{172}
\]

Using the same type of techniques employed in the case of Gallager codes (see Appendix C.2 for details), we obtain the following expression for the replicated partition function:

\[
\langle Z^n \rangle_{A,\xi,\zeta} = \prod_{j=1}^N \sum_{C_j} P_C(C_j) \prod_{l=1}^M \sum_{D_l} P_D(D_l)
\times \left( \frac{dq_0 dq_\alpha}{2\pi i} \right)^n \left( \frac{dr_0 dr_\alpha}{2\pi i} \right)^n
\times \exp \left[ \frac{MLNK}{K!L!} \sum_m^n \sum_\alpha q_\alpha m q_\alpha m \tau_\alpha m \right]
\times \frac{1}{N} \prod_{j=1}^N \Tr[S_j^\alpha] \left[ \exp \left[ F_\alpha \beta \xi \sum_\alpha S_j^\alpha \right] \right]
\times \int \frac{dZ_j}{Z_j^{C_j+1}} \exp \left[ \sum_{m=0}^n \sum_{(\alpha_1 \cdots \alpha_m)} q_{\alpha_1 \cdots \alpha_m} S_j^{\alpha_1} \cdots S_j^{\alpha_m} \right]
\]
\begin{align}
\times & \prod_{l=1}^{M} \text{Tr}_{\tau^a_l} \left[ \langle \exp \left[ F_n \beta \zeta \sum_{\alpha=1}^{n} \tau^\alpha_l \right] \rangle \zeta \right] \\
\times & \int \frac{dY_l}{2\pi i} \exp \left[ \sum_{m=0}^{n} \sum_{(\alpha_1, \ldots, \alpha_m)} \frac{Y_l^{\alpha_1} \cdots Y_l^{\alpha_m}}{Y_l^{D_k}} \left( \tau^\alpha_1 \cdots \tau^\alpha_m \right) \right], \quad (173)
\end{align}

where \( T_m = e^{-n\beta \gamma} \cosh^n(\beta \gamma) \tanh^m(\beta \gamma) \). Note that the above expression is an extension of Eq. (120).

The replica symmetry assumption is enforced by using the ansätze:

\[ q_{\alpha_1 \cdots \alpha_m} = \int dx \, \pi(x) \, x^m \quad \hat{q}_{\alpha_1 \cdots \alpha_m} = \int d\hat{x} \, \hat{\pi}(\hat{x}) \, \hat{x}^m \quad (174) \]

and

\[ r_{\alpha_1 \cdots \alpha_m} = \int dy \, \phi(y) \, y^m \quad \hat{r}_{\alpha_1 \cdots \alpha_m} = \int d\hat{y} \, \hat{\phi}(\hat{y}) \, \hat{y}^m. \quad (175) \]

By plugging the above ansätze, using the limit \( \gamma \to \infty \) and standard techniques (see Appendix C.3 for details) the following expression for the free-energy:

\[ f = \frac{1}{\beta} \text{Extr}_{[\hat{x}, \pi, \hat{\phi}, \phi]} \left\{ \alpha \ln 2 \right. \]
\[ + \, \overline{\mathcal{C}} \int dx \, \pi(x) \, d\hat{x} \, \hat{\pi}(\hat{x}) \ln (1 + x \hat{x}) \]
\[ + \, \alpha \overline{D} \int dy \, \phi(y) \, d\hat{y} \, \hat{\phi}(\hat{y}) \ln (1 + y \hat{y}) \]
\[ - \, \alpha \sum_{C} \mathcal{P}_C \int \left[ \prod_{j=1}^{K} \pi_j(x_j) \right] \left[ \prod_{l=1}^{L} \phi_l(y_l) \right] \ln \left( 1 + \prod_{j=1}^{K} x_j \prod_{l=1}^{L} y_l \right) \]
\[ - \, \sum_{C} \mathcal{P}_C \int \left[ \prod_{j=1}^{C} \pi_j(x_j) \right] \left[ \prod_{l=1}^{D} \phi_l(y_l) \right] \ln \left( \sum_{\sigma_{\pm} = 1}^{C} \, \left[ \prod_{j=1}^{C} \left( 1 + \sigma \hat{x}_j \right) \right] \right) \]
\[ - \, \alpha \sum_{D} \mathcal{P}_D \int \left[ \prod_{l=1}^{D} \phi_l(y_l) \right] \left[ \prod_{l=1}^{D} \left( 1 + \sigma \hat{y}_l \right) \right] \ln \left( \sum_{\sigma_{\pm} = 1}^{D} \, \left[ \prod_{l=1}^{D} \left( 1 + \sigma \hat{y}_l \right) \right] \right) \left\}, \right. \]

where \( \overline{\mathcal{C}} = \sum_{C} C \, \mathcal{P}_C(C), \overline{D} = \sum_{D} D \, \mathcal{P}_D(D) \) and \( \alpha = M/N = \mathcal{C}/K \).

By performing the extremization above, restricted to the space of normalized functions, we find the following saddle-point equations:

\[ \hat{\pi}(\hat{x}) = \int \prod_{j=1}^{K-1} dx_j \pi(x_j) \prod_{l=1}^{L} dy_l \phi(y_l) \delta \left[ \hat{x} - \prod_{j=1}^{K-1} x_j \prod_{l=1}^{L} y_l \right] \quad (177) \]

\[ \pi(x) = \frac{1}{\mathcal{C}} \sum_{C} C \, \mathcal{P}_C \int \prod_{l=1}^{C-1} d\hat{x}_l \, \hat{\pi}(\hat{x}_l) \]
\[ \times \left\langle \delta \left[ x - \tanh \left( \beta F_x \xi + \sum_{l=1}^{C-1} \text{atanh} \, \hat{x}_l \right) \right] \right\rangle_{\xi}, \]
\[
\hat{\phi}(\hat{y}) = \int \prod_{l=1}^{L-1} dy_l \phi(y_l) \prod_{j=1}^{K} dx_j \pi(x_j) \delta \left[ \hat{y} - \prod_{l=1}^{L-1} y_l \prod_{j=1}^{K} x_j \right]
\]

\[
\phi(y) = \frac{1}{D} \sum_{D} D \mathcal{P}_D \int \prod_{l=1}^{D-1} d\hat{y}_l \hat{\phi}(\hat{y}_l)
\times \left\langle \delta \left[ y - \tanh \left( \beta F_s \xi + \sum_{l=1}^{D-1} \text{atanh} \ \hat{y}_l \right) \right] \right\rangle_{\xi}.
\]

The typical overlap \( \rho = \langle \frac{1}{N} \sum_{j=1}^{N} \xi_j \hat{\xi}_j \rangle_{A,\zeta} \) between the estimate \( \hat{\xi}_j = \text{sgn}(\langle S_j \rangle_{\beta N}) \) and the actual signal \( \xi_j \) is given by (see Appendix A.3):

\[
\rho = \int dh \ P(h) \ \text{sgn}(h) \tag{178}
\]

\[
P(h) = \sum_{C} \mathcal{P}_C(C) \int \prod_{l=1}^{C} d\hat{x}_l \ \hat{\pi}(\hat{x}_l)
\times \left\langle \delta \left[ h - \tanh \left( \beta F_s \xi + \sum_{l=1}^{C} \text{atanh} \ \hat{x}_l \right) \right] \right\rangle_{\xi}.
\]

The intensive entropy is simply \( s = \beta \frac{\partial f}{\partial \beta} \) yielding:

\[
s = \beta (u(\beta) - f) \tag{179}
\]

\[
u = - \sum_{C} \mathcal{P}_C \int \prod_{j=1}^{C} d\hat{x}_j \ \hat{\pi}(\hat{x}_j) \left\langle F_s \xi \sum_{\sigma = \pm 1} \sigma e^{\sigma \beta F_s \xi} \prod_j (1 + \sigma \hat{x}_j) \right\rangle_{\xi}
\]

\[- \alpha \sum_{D} \mathcal{P}_D \int \prod_{j=1}^{D} d\hat{y}_j \ \hat{\phi}(\hat{y}_j) \left\langle F_n \sum_{\sigma = \pm 1} \sigma e^{\sigma \beta F_n \xi} \prod_j (1 + \sigma \hat{y}_j) \right\rangle_{\xi},
\]

where starred distributions are solutions for (177) and \( u(\beta) \) is the internal energy density.

For optimal decoding the temperature must be chosen to be \( \beta = 1 \) (Nishimori temperature) and the fields are

\[
F_s = \frac{1}{2} \ln \left( \frac{1 - p_{\xi}}{p_{\xi}} \right) \quad F_n = \frac{1}{2} \ln \left( \frac{1 - p}{p} \right).
\]

5.4. Probability propagation decoding

In Sections 3 and 4 we derived probability propagation equations firstly by assuming a set of factorization properties and writing a closed set of equations that allowed the iterative computation of the (approximate) marginal posterior and secondly by computing local magnetizations on the interior of a Husimi cactus (Bethe approximation). The two methods are equivalent as the factorization properties assumed in the former are encoded in the geometry of the lattice assumed in the latter.

Here we use insights provided in the last sections to build a decoding algorithm for MN codes directly. From the replica symmetric free-energy (176) we can write the
following Bethe free-energy:

\[
\mathcal{F}(\mathbf{m}, \mathbf{\hat{m}}) = \frac{M}{N} \ln 2 + \frac{1}{N} \sum_{\mu=1}^{M} \sum_{i \in \mathcal{L}_{s}(\mu)} \ln \left(1 + m_{\mu i}^{s} \hat{m}_{\mu i}^{s}\right)
\]

\[
+ \frac{1}{N} \sum_{\mu=1}^{M} \sum_{j \in \mathcal{L}_{n}(\mu)} \ln \left(1 + m_{\mu j}^{n} \hat{m}_{\mu j}^{n}\right)
\]

\[- \frac{1}{N} \sum_{\mu=1}^{M} \ln \left(1 + \mathcal{J}_{\mu} \prod_{i \in \mathcal{L}_{s}(\mu)} m_{\mu i}^{s} \prod_{j \in \mathcal{L}_{n}(\mu)} m_{\mu j}^{n}\right)
\]

\[- \frac{1}{N} \sum_{i=1}^{N} \ln \left[ \sum_{\sigma = \pm} e^{\sigma F_{s}} \prod_{\mu \in \mathcal{M}_{s}(i)} \left(1 + \sigma \hat{m}_{\mu i}^{s}\right)\right]
\]

\[- \frac{1}{N} \sum_{j=1}^{M} \ln \left[ \sum_{\sigma = \pm} e^{\sigma F_{n}} \prod_{\mu \in \mathcal{M}_{n}(j)} \left(1 + \sigma \hat{m}_{\mu j}^{n}\right)\right].
\]

The variables \(m_{\mu j}^{s}\) (\(m_{\mu j}^{n}\)) are cavity effective magnetizations of signal (noise) bits interacting through the coupling \(\mu\), obtained by removing one of the \(C\) couplings in \(\mathcal{M}_{s}(j)\) (\(\mathcal{M}_{n}(j)\)) from the system. The variables \(\hat{m}_{\mu j}^{s}\) (\(\hat{m}_{\mu j}^{n}\)) correspond to effective magnetizations of signal (noise) bits due to the coupling \(\mu\) only.

The decoding solutions are fixed points of the free-energy (181) given by:

\[
\frac{\partial \mathcal{F}(\mathbf{m}, \mathbf{\hat{m}})}{\partial m_{\mu j}^{s}} = 0 \quad \frac{\partial \mathcal{F}(\mathbf{m}, \mathbf{\hat{m}})}{\partial \hat{m}_{\mu j}^{s}} = 0
\]

\[
\frac{\partial \mathcal{F}(\mathbf{m}, \mathbf{\hat{m}})}{\partial m_{\mu j}^{n}} = 0 \quad \frac{\partial \mathcal{F}(\mathbf{m}, \mathbf{\hat{m}})}{\partial \hat{m}_{\mu j}^{n}} = 0
\]

The solutions for the above equations are the equations being solved by the probability propagation decoding algorithm:

\[
m_{\mu j}^{s} = \tanh \left[ \sum_{\nu \in \mathcal{M}_{s}(\mu) \setminus \mu} \text{atanh}(\hat{m}_{\nu j}^{s}) + F_{s}\right]
\]

\[
\hat{m}_{\mu j}^{s} = \mathcal{J}_{\mu} \prod_{i \in \mathcal{L}_{s}(\mu) \setminus j} m_{i j}^{s} \prod_{l \in \mathcal{L}_{n}(\mu)} m_{l j}^{n};
\]

\[
m_{\mu j}^{n} = \tanh \left[ \sum_{\nu \in \mathcal{M}_{n}(\mu) \setminus \mu} \text{atanh}(\hat{m}_{\nu j}^{n}) + F_{n}\right]
\]

\[
\hat{m}_{\mu j}^{n} = \mathcal{J}_{\mu} \prod_{i \in \mathcal{L}_{s}(\mu) \setminus j} m_{i j}^{s} \prod_{l \in \mathcal{L}_{n}(\mu) \setminus j} m_{l j}^{n};
\]

The estimate for the message is \(\hat{\xi}_{j} = \text{sgn}(m_{j}^{s})\), where \(m_{j}^{s}\) is the local magnetization due to all couplings linked to the site \(j\) can be computed as:

\[
m_{j}^{s} = \tanh \left[ \sum_{\nu \in \mathcal{M}_{s}(j)} \text{atanh}(\hat{m}_{\nu j}^{s}) + F_{s}\right]
\]
One possibility for the decoding dynamics is to update Eqs. (183) and (185) until a certain halting criteria is reached, and then computing the estimate for the message using equation (187). The initial conditions are set to reflect the prior knowledge about the message \( m_{\mu j}^n(0) = 1 - 2p_{\xi} \) and noise \( m_{\mu}^n(0) = 1 - 2p \).

As the prior information is limited, a polynomial time decoding algorithm (like PP) will work only if the solution is unique or the initial conditions are inside the correct basin of attraction. In this case the \( 2(NK + MC) \) equations (181) only need to be iterated an \( O(1) \) number of times to get a successful decoding. On the other hand, when there are many solutions, it is possible to obtain improved decoding in exponential time by choosing random initial conditions and comparing free-energies of the solutions obtained, selecting a global minimum.

Observe that the free-energy described here is not equivalent to the variational mean-field free-energy introduced in [Mac95, Mac99]. Here no essential correlations are disregarded except those related to the presence of loops are disregarded.

In the next section we will analyze the landscape of the replica symmetric free-energy for three families of constraction parameters and will be able to predict the practical performance of a PP decoding algorithm.

5.5. Equilibrium results and decoding performance

The saddle-point equations (177) can be solved by using Monte-Carlo integration iteratively. In this section we show that MN codes can be divided, as far as performance is concerned, into three parameter groups: \( K \geq 3, K = 2 \) and \( K = 1, L > 1 \).

We, therefore, treat each these cases separately in the following.

5.5.1. Analytical solution: the case of \( K \geq 3 \)  
Replica symmetric results for the cases of \( K \geq 3 \) can be obtained analytically, therefore we focus first on this simple case. For unbiased messages \( (F_s = 0) \), we can easily verify that the ferromagnetic state, characterised by \( \rho = 1 \), and the probability distributions

\[
\pi(x) = \delta(x - 1) \\
\hat{\pi}(\hat{x}) = \delta(\hat{x} - 1) \\
\phi(y) = \delta(y - 1) \\
\hat{\phi}(\hat{y}) = \delta(\hat{y} - 1)
\]

and the paramagnetic state of \( \rho = 0 \) with the probability distributions

\[
\pi(x) = \delta(x) \\
\hat{\pi}(\hat{x}) = \delta(\hat{x}) \\
\hat{\phi}(\hat{y}) = \delta(\hat{y}) \\
\phi(y) = \frac{1 + \tanh(F_n)}{2} \delta(y - \tanh(F_n)) + \frac{1 - \tanh(F_n)}{2} \delta(y + \tanh(F_n)),
\]
satisfy replica symmetric saddle-point equations (177). Other solutions could be obtained numerically. To check for that, we represented the distributions with histograms of 20000 bins and iterated Eqs.(177) 100 – 500 times with $2 \times 10^5$ Monte-Carlo sampling steps for each iteration. No solutions other than ferromagnetic and paramagnetic have been observed.

The thermodynamically dominant state is found by evaluating the free-energy of the two solutions using Eq.(176), which yields

$$f_{\text{FERRO}} = -\frac{C}{K} F_n \tanh(F_n),$$

for the ferromagnetic solution and

$$f_{\text{PARA}} = \frac{C}{K} \ln 2 - \ln 2 - \frac{C}{K} \ln (2 \cosh(F_n)),$$

for the paramagnetic solution.

Figure 24(a) describes schematically the nature of the solutions for this case, in terms of the replica symmetric free-energy and overlap obtained, for various noise levels $p$ and unbiased messages $p_\xi = 1/2$. The coexistence line in the code rate versus noise level plane is given by

$$f_{\text{FERRO}} - f_{\text{PARA}} = \frac{\ln 2}{R_c} [R_c - 1 + H_2(p)] = 0.$$ (192)

This can be rewritten as

$$R_c = 1 - H_2(p) = 1 + p \log_2(p) + (1 - p) \log_2(1 - p),$$

which coincides with channel capacity and is represented in Fig. 25(a) together with the overlap $\rho$ as a function of the noise level $p$.

Equation (193) seems to indicate that all constructions with $K \geq 3$ may attain error-free data transmission for $R < R_c$ in the limit where both message and codeword lengths $N$ and $M$ become infinite, thus saturating Shannon’s bound. However, as described in Fig.24(a), the paramagnetic state is also stable for any noise level, what has dynamical implications if a replica symmetric free-energy is to be used for decoding (as is the case in probability propagation decoding).

To validate the solutions obtained we have to make sure that the entropy is positive. Entropies can be computed by simply plugging distributions (189) and (190) into Eq.(179). The energy densities for the unbiased case are $u = u_{\text{PARA}} = u_{\text{FERRO}} = -\alpha F_n (1 - 2p)$, since the Nishimori condition is employed (see Appendix B.3). Ferromagnetic entropies are $s_{\text{FERRO}} = u - f_{\text{FERRO}} = 0$ and

$$s_{\text{PARA}} = u - f_{\text{PARA}} = -\alpha F_n (1 - 2p) - \frac{C}{K} \ln 2 + \ln 2 + \frac{C}{K} \ln (2 \cosh(F_n)).$$ (194)

It can be seen by using a simple argument that $s_{\text{PARA}}$ is negative below $p_c$. For $p < p_c$, $f_{\text{PARA}} > f_{\text{FERRO}}$ and $u - s_{\text{PARA}} > u - s_{\text{FERRO}}$.

This indicates that the distribution (190) is non-physical below $p_c$, despite being a solution of replica symmetric saddle-point equations. This result seems to indicate
Figure 24. Figures in the left side show schematic representations free-energy landscapes while figures on the right show overlaps $\rho$ a function of the noise level $p$; thick and thin lines denote stable solutions of lower and higher free energies respectively, dashed lines correspond to unstable solutions. (a) $K \geq 3$ - The solid line in the horizontal axis represents the phase where the ferromagnetic solution ($F, \rho = 1$) is thermodynamically dominant. The paramagnetic solution ($P, \rho = 0$) becomes dominant at $p_c$, that coincides with the channel capacity. (b) $K = 2$ - The ferromagnetic solution and its mirror image are the only minima of the free-energy up to $p_s$ (solid line). Above $p_s$ sub-optimal ferromagnetic solutions ($F', \rho < 1$) emerge. The thermodynamic transition occurs at $p_3$ is below the maximum noise level given by the channel capacity, which implies that these codes do not saturate Shannon’s bound even if optimally decoded. (c) $K = 1$ - The solid line in the horizontal axis represents the range of noise levels where the ferromagnetic state ($F$) is the only minimum of the free-energy. The sub-optimal ferromagnetic state ($F'$) appears in the region represented by the dashed line. The dynamical transition is denoted by $p_s$, where $F'$ first appears. For higher noise levels, the system becomes bistable and an additional unstable solution for the saddle point equations necessarily appears. The thermodynamical transition occurs at the noise level $p_1$ where $F'$ becomes dominant.
that the replica symmetric free-energy does not provide the right description below $p_c$. A simple alternative, is to use the frozen spins solution as the formulation of a theory with replica symmetry breaking for highly diluted systems is a difficult task (see, for example, [WS88, Mon98b]).

Nevertheless, the practical performance of the probability propagation decoding is described by the replica symmetric theory, the presence of paramagnetic stable states implies the failure of PP decoding at any noise level. Even without knowing the correct physics below $p_c$, it is possible to use an exhaustive search for the global minimum of the free-energy in Section 5.4 to attain Shannon's bound in exponential time.

5.5.2. The case of $K = 2$ - All codes with $K \geq 3$ potentially saturate Shannon's bound and are characterized by a first order phase transition between the ferromagnetic and paramagnetic solutions. Solutions for the case with $K = 2$ can be obtained numerically, yielding significantly different physical behavior as shown in Fig.24(b).

At very large noise levels, the paramagnetic solution (190) gives the unique extremum of the free-energy until the noise level reaches $p_1$, at which the ferromagnetic solution (189) of higher free-energy becomes locally stable. As the noise level decreases to $p_2$ the paramagnetic solution becomes unstable and a sub-optimal ferromagnetic solution and its mirror image emerge. Those solutions have lower free-energy than the ferromagnetic solution until the noise level reaches $p_3$. Below $p_3$, the ferromagnetic solution becomes the global minimum of the free-energy, while the sub-optimal ferromagnetic solutions remain locally stable. However, the sub-optimal solutions disappear at the spinodal noise level $p_s$ and the ferromagnetic solution (and its mirror image) becomes the unique stable solution of the saddle-point Eqs.(177).

The analysis implies that $p_3$, the critical noise level below which the ferromagnetic solution becomes thermodynamically dominant, is lower than $p_c = H^{-1}(1 - R)$ which corresponds to Shannon's bound. Namely, $K = 2$ does not saturate Shannon's bound in contrast to $K \geq 3$ codes even if decoded in exponential time. Nevertheless, it turns out that the free-energy landscape, with a unique minimum for noise levels $0 < p < p_s$, offers significant advantages in the decoding dynamics comparing to that of codes with $K \geq 3$, allowing for the successful use of polynomial time probability propagation decoding.

5.5.3. The case of $K = 1$ and general $L > 1$ - The choice of $K = 1$, independently of the value chosen for $L > 1$, exhibits a different behavior presented schematically in Fig.24(c); also in this case there are no simple analytical solutions and all solutions in this scenario but the ferromagnetic one have been obtained numerically. The first important difference to be noted is that the paramagnetic state (190) is no longer a solution of the saddle-point equations (177) and is being replaced by a sub-optimal ferromagnetic state, very much like Gallager codes. Convergence to $\rho = 1$ solution can only be guaranteed for noise levels $p < p_s$, where only the ferromagnetic solution is present.

The $K = 1$ codes do not saturate Shannon's bound in practice, however, we have
Figure 25. Transition lines in the plane rate $R$ versus the flip rate $p$, obtained from numerical solutions and the TAP approach ($N = 10^4$), and averaged over 10 different initial conditions with error bars much smaller than the symbols size. (a) Numerical solutions for $K = L = 3$, $C = 6$ and varying input bias $f_s$ ($\Box$) and TAP solutions for both unbiased (+) and biased (\(\diamond\)) messages; initial conditions were chosen close to the analytical ones. The critical rate is multiplied by the source information content to obtain the maximal information transmission rate, which clearly does not go beyond $R = 3/6$ in the case of biased messages; for unbiased patterns $H_2(f_s) = 1$. (b) For the unbiased case of $K = L = 2$; initial conditions for the TAP (+) and the numerical solutions (\(\diamond\)) were chosen to be of almost zero magnetization. (c) For the case of $K = 1$, $L = 2$ and unbiased messages. We show numerical solutions of the analytical equations (\(\diamond\)) and those obtained by the TAP approach (+). The dashed line indicates the performance of $K = L = 2$ codes for comparison. Codes with $K = 1$, $L = 2$ outperform $K = L = 2$ for code rates $R < 1/3$. 
found that at rates $R < 1/3$ they outperform the $K = L = 2$ code (see Fig.25) while offering improved decoding times when probability propagation is used. Studying the replica symmetric free-energy in this case shows that as the corruption rate increases, sub-optimal ferromagnetic solutions (stable and unstable) emerge at the spinodal point $p_\nu$. When the noise increases further this sub-optimal state becomes the global minimum at $p_\nu$, dominating the system’s thermodynamics. The transition at $p_\nu$ must occur at noise levels lower or equal to the value predicted by Shannon’s bound.

In Fig.26 we show free-energy values computed for a given code rate and several values of $L$, denoting Shannon’s bound by a dashed line; the thermodynamic transition observed numerically (i.e. the point where the ferromagnetic free-energy equals the sub-optimal ferromagnetic free-energy) is closely below Shannon’s bound within the numerical precision used. Spinodal noise levels are indicated by arrows. In Fig.27 we show spinodal noise levels as a function of $L$ as predicted by the replica symmetric theory (circles) and obtained by running PP decoding of codes with size $10^4$. The optimal parameter choice is $L = 2$.

Due to the simplicity of the saddle-point equations (177) we can deduce the asymptotic behavior of $K = 1$ and $L = 2$ codes for small rates (large $C$) by computing the two first cumulants of the distributions $\pi, \hat{x}, \phi$ and $\hat{\phi}$ (Gaussian approximation). A decoding failure corresponds to $\langle h \rangle \sim O(1)$ and $\sigma_h^2 \sim O(1)$. It implies that $\langle \hat{x} \rangle \sim O(1/C)$ and $\sigma_{\hat{x}} \sim O(1/C)$. For that $y$ must be small and we can use

\begin{figure}[h]
\centering
\includegraphics[width=0.5\textwidth]{fig26}
\caption{Free-energies obtained by solving the analytical equations using Monte-Carlo integrations for $K = 1$, $R = 1/6$ and several values of $L$. Full lines represent the ferromagnetic free-energy (FERRO, higher on the right) and the suboptimal ferromagnetic free-energy (higher on the left) for values of $L = 2, \ldots, 7$. The dashed line indicates Shannon’s bound and the arrows represent the spinodal point values $p_\nu$ for $L = 2, \ldots, 7$. The thermodynamic transition coincides with Shannon’s bound.}
\end{figure}
\[
\text{atanh}(\tanh(y_1)\tanh(y_2)) \approx y_1 y_2 \text{ and write:}
\]
\[
\langle x \rangle \sim O(1) \quad \sigma_x^2 \sim O(1)
\]
\[
\langle \hat{x} \rangle \approx \langle y \rangle^2
\]
\[
\sigma_{\hat{x}}^2 \approx \langle y^2 \rangle^2 - \langle y \rangle^4
\]
\[
\langle y \rangle = \langle \hat{y} \rangle + (1 - 2p)F_n \quad \sigma_y^2 = \sigma_{\hat{y}}^2 + 4f(1-p)F_n^2
\]
\[
\langle \hat{y} \rangle \approx \langle \tanh(x) \rangle \langle y \rangle
\]
\[
\sigma_{\hat{y}}^2 \approx \langle \tanh^2(x) \rangle \langle y^2 \rangle - \langle \tanh(x) \rangle^2 \langle y \rangle^2
\]

To simplify further we can assume that \( p \to 0.5 \). Therefore \( F_n \approx (1 - 2p) \). The critical observation is that in order to have \( \langle h \rangle \sim O(1) \) we need that \( \hat{x} \sim O(1/C) \) and consequently \( \langle y \rangle \sim O(1/\sqrt{C}) \). Manipulating the set of equations above:

\[
\langle y \rangle \approx \langle \tanh(x) \rangle \langle y \rangle + (1 - 2f)^2
\]

By imposing the condition over \( \langle y \rangle: C^{-1/2} \sim (1 - 2p)^2(1 - \langle \tanh(x) \rangle)^{-1} \)

In terms of the code rate \( R = 1/C \):

\[
R \sim \frac{(1 - 2p)^4}{(1 - \langle \tanh(x) \rangle)^2}
\]

The asymptotic behavior of Shannon’s bound is given by:

\[
R \sim \frac{(1 - 2p)^2}{\ln 2}
\]

Thus, the \( K = 1 \) and \( L = 2 \) codes are not optimal asymptotically (large \( C \) values). In Fig 28 we verify the relation (201) by iterating first cumulant equations in the delta approximation and first and second cumulant equations in the Gaussian approximation.
5.6. Error-correction: regular vs. irregular codes

Matrix construction irregularity can improve the practical performance of MN codes. This fact has been first reported in the information theory literature (see for example [Dav99, Dav98, LMSS98]). Here we analyze this problem by using the language and tools of statistical physics. We now use the simplest irregular constructions as an illustration, here, the connectivities of the signal matrix $C_s$ are described by a simple bimodal probability distribution:

$$P_C(C) = (1 - \theta) \delta(C - C_o) + \theta \delta(C - C_e).$$

The mean connectivity is $\bar{C} = (1 - \theta) C_o + \theta C_e$ and $C_o < \bar{C} < C_e$; bits in a group with connectivity $C_o$ will be referred as ordinary bits and bits in a group with connectivity $C_e$ as elite bits. The noise matrix $C_n$ is chosen to be regular.

To gain some insight on the effect of irregularity on solving the PP equations (183) and (185) we performed several runs starting from the fixed initial conditions $m_{ij}^s(0) = 1 - 2p$ and $m_{ij}^n(0) = 1 - 2p$ as prescribed in the last section. For comparison we also iterated the saddle-point equations (177) obtained by the replica symmetric (RS) analysis, setting the initial conditions to be $\pi_0(x) = (1 - p) \delta(x - m_{ij}^s(0)) + p \delta(x + m_{ij}^s(0))$ and $\rho_0(y) = (1 - p) \delta(y - m_{ij}^n(0)) + p \delta(y + m_{ij}^n(0))$, as suggested from the interpretation of the fields $\pi(x)$ and $\rho(y)$ in the last section.

In Fig.29(a) we show a typical curve for the overlap $\rho$ as a function of the noise level $p$. The RS theory agrees very well with PP decoding results. The addition of irregularity
improves the performance considerably. In Fig 29 (b) we show the free-energies of the two emerging states. The free-energy for the ferromagnetic state with overlap $\rho = 1$ is shown as a full line, the failure suboptimal ferromagnetic state (in Fig 29 (a) with overlap $\rho = 0.4$) is shown as a line marked with $\circ$. The transitions seen in Fig 29(a) are denoted by dashed lines. It is clear that they are far below the thermodynamic (T) transition, indicating that the system becomes trapped in suboptimal ferromagnetic states for noise levels $p$ between the observed transitions and the thermodynamic transition. The thermodynamic transition coincides with the upper bound (u.b.) in Section 5.1 and is very close to, but below, Shannon’s limit which is shown for comparison. Similar behavior was observed in regular MN codes with $K = 1$.

5.7. The spinodal noise level

The PP algorithm can be regarded as an iterative solution of fixed point equations for the free-energy (181) which is sensitive to the presence of local minima in the system. One can expect convergence to the global minimum of the free-energy from all initial conditions when there is a single minimum or when the landscape is dominated by the basin of attraction of this minimum when random initial conditions are used.

To analyze this point we run decoding experiments starting from initial conditions $m_{\mu j}^*(0)$ and $m_{\mu i}^*(0)$ that are random perturbations of the ferromagnetic solution drawn
from the following distributions:

\[ P (m^s_{\mu j}(0)) = (1 - \lambda_s) \delta (m^s_{\mu j}(0) - \xi_j) + \lambda_s \delta (m^s_{\mu j}(0) + \xi_j) \]  \hspace{1cm} (204)

and

\[ P (m^n_{\mu d}(0)) = (1 - \lambda_n) \delta (m^n_{\mu d}(0) - \tau_d) + \lambda_n \delta (m^n_{\mu d}(0) + \tau_d), \]  \hspace{1cm} (205)

where for convenience we choose \( 0 \leq \lambda_s = \lambda_n = \lambda \leq 0.5 \).

We performed PP decoding several times for different values of \( \lambda \) and noise level \( p \). For \( \lambda \leq 0.026 \) we observed that the system converges to the ferromagnetic state for all constructions, message biases \( p_\ell \) and noise levels \( p \) examined. It implies that this state is always stable. The convergence occurs for any \( \lambda \) for noise levels below the transition observed in practice.

These observations suggest that the ferromagnetic basin of attraction dominates the landscape up to some noise level \( p_s \). The fact that no other solution is ever observed in this region suggests that \( p_s \) is the noise level where suboptimal solutions actually appear, namely, it is the noise level that corresponds to the appearance of spinodal points in the free-energy. The same was observed for regular MN codes with \( K = 1 \) or \( K = 2 \).

We have shown that MN codes can be divided into three categories with different equilibrium properties: (i) \( K \geq 3 \), (ii) \( K = 2 \) and (iii) general \( L > 1, K = 1 \). In the next two subsections we will discuss these cases separately.
**Figure 31.** Spinodal noise level $p_s$ for irregular codes as a function of the message bias $p_\xi$. The construction is parameterized by $K = L = 3$, $C_o = 4$ and $C_e = 30$ with $\overline{C} = 15$. PP decoding is carried out with $N = 5000$ and a maximum of 500 iterations, and is represented by $+$, while theoretical RS solutions are represented by $\circ. The full line indicates Shannon's limit. Symbols are larger than the actual error bars.

5.7.1. Biased messages: $K \geq 3$  
To show how irregularity affects codes with this choice of parameters we choose $K, L = 3$, $C_o = 4$, $C_e = 30$ and biased messages with $p_\xi = 0.3$. These choices are arbitrary but illustrate what happens with the practical decoding performance. In Fig.30 we show the transition from the decoding phase to a failure phase as a function of the noise level $p$ for several rates $R$ in both regular and irregular codes. Practical decoding ($\circ$ an $\ast$) results are obtained for systems of size $N = 5000$ with a maximum number of iterations set to 500. Random initial conditions are chosen and the whole process repeated 20 times. The practical transition point is found when the number of failures equals the number of successes.

These experiments were compared with the theoretical values for $p_s$ obtained by solving the RS saddle-point equations (177) (represented as $+$ and $\ast$ in Fig. 30) and finding the noise level for which a second solution appears. For comparison the coding limit is represented in the same figure by a full line.

As the constructions used are chosen arbitrarily one can expect that these transitions can be further improved, even though the improvement shown in Fig.30 is already fairly significant.

The analytical solution obtained for $K \geq 3$ and unbiased messages $p_\xi = 1/2$, implies that the system is bistable for arbitrary code constructions when these parameters are chosen. The spinodal noise level is then $p_s = 0$ in this case and cannot be improved by adding irregularity to the construction. Up to the noise level $p_\xi$ the ferromagnetic solution is the global minimum of the free-energy, and therefore Shannon's limit is achievable in exponential time, however, the bistability makes these constructions
unsuitable for practical decoding with a PP algorithm when unbiased messages are considered.

The situation improves when biased messages are used. Fixing the matrices $C_n$ and $C_s$ one can determine how the spinodal noise level $p_s$ depends on the bias $p_k$. In Fig.31 we compare simulation results with the theoretical predictions of $p_s$ as a function of $p_k$. The spinodal noise level $p_s$ collapses to zero as $p_k$ increases towards the unbiased case. It obviously suggests using biased messages for practical MN codes with parameters $K \geq 3$ and PP decoding.

The qualitative pictures of the energy landscape for coding with biased and unbiased messages with $K \geq 3$ differ significantly. In Fig.32 this landscape is sketched as a function of the noise level $p$ for a given bias. Up to the spinodal noise level $p_s$ the landscape is totally dominated by the ferromagnetic state $F$. At the spinodal noise level another suboptimal state $F'$ emerges, dominating the decoding dynamics. At $p_s$ the suboptimal state $F'$ becomes the global minimum. The bold horizontal line represents the region where the ferromagnetic solution with $\rho = 1$ dominates the decoding dynamics. In the region represented by the dashed line decoding dynamics is dominated by suboptimal ferromagnetic $\rho < 1$ solutions.

5.7.2. Unbiased messages: For the remaining parameter choices, namely general $L > 1$, $K = 1$ and $K = 2$, it was shown that unbiased coding is generally possible yielding close to Shannon’s limit performance.

The $K \geq 3$ case the practical performance is defined by the spinodal noise level $p_s$ and the addition of irregularity modifies $p_s$.

In the general $L$, $K = 1$ family we illustrate the effect of irregularity by the choice of $L = 2$, $C_o = 4$ and $C_e = 10$. In Fig.33 we show the transitions observed by performing
20 decoding experiments with messages of length $N = 5000$ and a maximal number of iterations set to 500 (+ for regular and * for irregular). We compare the experimental results with theoretical predictions based on the RS saddle-point equations (177) (◊ for regular and ◦ for irregular). Shannon’s limit is represented by a full line. The improvement is modest, as expected, since regular codes already present close to optimal performance. Discrepancies between the theoretical and numerical results are due to finite size effects.

We also performed a set of experiments using $K = L = 2$ with $C_o = 3$ and $C_e = 8$, the same system size $N = 5000$ and maximal number of decoding iterations 500. The transitions obtained experimentally and predicted by theory are shown in Fig.34.

6. Cascading Codes

Kanter and Saad (KS) recently proposed a variation of MN codes that has been shown to be capable of attaining close to channel capacity performance and outperforming Turbo codes [KS99b, KS00b, KS00a]. The central idea is to explore the superior dynamical properties (i.e. large basin of attraction) of MN codes with $K = 1, 2$ and the potential for attaining channel capacity of MN codes with $K > 2$ by introducing constructions with intermediate properties. This is done by employing irregular constructions like the one depicted in Fig. 36, with the number of non-zero elements per row set to several different values $K_1, \cdots, K_m$. 

\begin{figure}
\centering
\includegraphics[width=0.5\textwidth]{figure33}
\caption{Spinodal noise level $p_s$ for regular and irregular codes. The constructions are of $K = 1$ and $L = 2$, irregular codes are parameterized by $C_o = 4$ and $C_e = 10$. PP decoding is carried out with $N = 5000$ and a maximum of 500 iterations; they are denoted by + (regular) and * (irregular). Numerical solutions for RS equations are denoted by ◊ (regular) and ◦ (irregular). The coding limit is represented by a line. Symbols are larger than the actual error bars.}
\end{figure}
In Fig. 35 we show a performance comparison (presented in [KS00b]) of Turbo, KS and Gallager codes with optimized irregular constructions [RSU01] for a memoryless Gaussian channel. The bit error probability $p_b$ is plotted against the signal to noise ratio in decibels ($10 \log_{10}(S/N)$) for codes of sizes $N = 1000$ and $N = 10000$.

The introduction of multi-spin interactions of several different orders and of more structured matrices makes the statistical physics of the problem much harder to solve. We, therefore, adopt a different approach: first we write the probability propagation equations and find an appropriate macroscopic description in terms of field distributions, we then solve saddle-point like equations for the field distributions to find the typical performance.

Cascading codes are specific constructions of MN codes. The signal matrix $C_s$ is defined by $m$ random sub-matrices with $K_1, K_2, \ldots, K_m$ non-zero elements per row respectively. The matrix $C_n$ is composed of two sub-matrices: $C_{n_{ij}}^{(1)} = \delta_{i,j} + \delta_{i,j+\Delta}$ and $C_{n_{ij}}^{(2)} = \delta_{i,j}$. The inverse $C_n^{-1}$ used in the encoding process is easily obtainable. In Fig. 36 we represent a KS code with three signal sub-matrices, the non-zero elements in the noise matrix $C_n$ are denoted by lines, we also represent the inverse of the noise matrix $C_n^{-1}$.

The signal matrix $C_s$ is subdivided into $M_j \times N$ sub-matrices, with $j = 1, \ldots, m$. The total number of non-zero elements is given by $NC = \sum_{j=1}^{m} M_j K_j$ what yields $C = \sum_{j=1}^{m} \alpha_j K_j$, where $\alpha_j = M_j / N$. The code construction is, therefore, parameterized by the set $\{(\alpha_j, K_j)\}$. If we fix $\{K_j\}$, the parameters $\{\alpha_j\}$ completely specify the
construction. A further constraint to the parameters set \( \{\alpha_j\} \) is provided by the choice of a code rate, as the inverse code rate is \( \alpha = M/N = \sum_{j=1}^{M} \alpha_j \).

Encoding and decoding using cascading codes are performed in exactly the same fashion as described in 5 for MN codes. A binary vector \( t \in \{0, 1\}^M \) defined by

\[
t = G\xi \pmod{2},
\]

(206)

is produced, where all operations are performed in the field \( \{0, 1\} \) and are indicated by \( \pmod{2} \). The code rate is \( R = N/M \). The generator matrix \( G \) is a \( M \times N \) dense matrix defined by

\[
G = C_n^{-1}C_s \pmod{2}.
\]

(207)

The transmitted vector \( r \) is then corrupted by noise. Assuming a memoryless binary symmetric channel (BSC), noise is represented by a binary vector \( \zeta \in \{0, 1\}^M \) with components independently drawn from the distribution \( P(\zeta) = (1-p)\delta(\zeta)+p\delta(\zeta-1) \).

The received vector is

\[
r = Gr + \zeta \pmod{2}.
\]

(208)

Decoding is performed by computing the syndrome vector

\[
z = C_n r = C_s\xi + C_n\zeta \pmod{2},
\]

(209)

from which an estimate \( \hat{\xi} \) for the message can be obtained.
6.1. Typical PP decoding and saddle-point like equations

In this section we show how a statistical description for the typical PP decoding can be constructed without using replica calculations. To keep the analysis as simple as possible we exemplify the procedure with a KS code with two signal matrices denoted \(1s\) and \(2s\) and two noise sub-matrices denoted \(1n\) and \(2n\). The channel is chosen to be a memoryless binary symmetric channel (BSC). The number of non-zero elements per row is \(K_1\) and \(K_2\), respectively, and the inverse rate is \(\alpha = \alpha_1 + \alpha_2\). Therefore, for a fixed code rate, the code construction is specified by a single parameter \(\alpha_1\). We present one code in this family in Fig.37.

The PP decoding dynamics for these codes is described by Eqs. (185). However, due to the irregular character of the construction, sites inside each one of the sub-matrices are connected differently. Reminding the statistical physics formulation of MN codes presented in Section 5.2, non-zero row elements in the matrices depicted in Fig.37...
correspond to sites taking part in one multi-spin interaction. Therefore, signal sites in the sub-matrix $1s$ interact with other $K_1 - 1$ signal sites in $1s$ and exactly two noise sites in $1n$. Moreover, the same site takes part in other $\alpha_1 K_1 + \alpha_2 K_2 - 1$ multi-spin couplings in both $1s$ and $2s$. Sites in sub-matrix $2s$ interact with one noise site in $2n$ and $K_2 - 1$ signal sites in $2s$, taking part in other $\alpha_1 K_1 + \alpha_2 K_2 - 1$ multi-spin interaction. Noise sites in the sub-matrix $1n$ interact with another noise site and with $K_1$ signal sites in $1s$. Finally, noise sites in $2n$ interact with $K_2$ sites in $2s$. Thus, the Hamiltonian for a KS code takes the following form:

$$
\mathcal{H} = -\gamma \sum_{\mu=1}^{M_1} (J_{\mu} S_{i_1} \cdots S_{i_{K_1}} \tau_{\mu, \mu+\Delta} - 1) \\
- \gamma \sum_{\mu=M_1+1}^{M} (J_{\mu} S_{i_1} \cdots S_{i_{K_2}} \tau_{\mu} - 1) - F_n \sum_{i=1}^{M_1} n_i - F_s \sum_{i=1}^{N} S_i,
$$

(210)

where $J_{\mu} = \xi_{i_1} \cdots \xi_{i_{K_1}} \zeta_{\mu+\Delta}$, for $\mu = 1, \cdots, M_1$ and $J_{\mu} = \xi_{i_1} \cdots \xi_{i_{K_2}} \zeta_{\mu}$ for $\mu = M_1 + 1, \cdots, M$. Additionally, Nishimori’s condition requires that $\gamma \to \infty$, $F_s = \text{atanh}(1 - 2p)$ and $F_n = \text{atanh}(1 - 2p)$, where the prior probabilities are defined as in the previous chapters.

We can write PP decoding equations for each one of the sub-matrices $1s$, $2s$, $1n$ and $2n$. The shaded regions in Fig.37 have to be described by different equations, but can be disregard if the width $\Delta$ is of $O(1)$, implying $\Delta/N \to 0$ for $N \to \infty$.

For the sub-matrix $1s$ we have:

$$
m_{\mu j}^{(1s)} = \text{tanh} \left[ \sum_{\nu \in \mathcal{M}_1(j) \setminus \mu} \text{atanh}(\hat{m}_{\nu j}^{(1s)}) + \sum_{\nu \in \mathcal{M}_2(j)} \text{atanh}(\hat{m}_{\nu j}^{(2s)}) + F_s \right]
$$
\[
\tilde{m}_{\mu j}^{(1s)} = J_{\mu} m_{\mu j}^{(1m)} m_{\mu+\Delta}^{(1m)} \prod_{l \in E_1(\mu) \setminus j} m_{pl}^{(1s)},
\]

(211)

where the second equation represents interactions with two noise sites and and \( K_1 - 1 \)
signal sites. The first equation represents the \( \alpha_1 K_1 + \alpha_2 K_2 - 1 \) multi-spin interactions
the site \( j \) participates in.

Similarly, for the sub-matrix 2s we have:

\[
m_{\mu j}^{(2s)} = \tanh \left[ \sum_{\nu \in M_2(j)} \tanh(\tilde{m}_{\nu j}^{(1s)}) + \sum_{\nu \in M_2(j) \setminus \nu} \tanh(\tilde{m}_{\nu j}^{(2s)}) + F_s \right]
\]

\[
\tilde{m}_{\mu j}^{(2s)} = J_{\mu} m_{\mu j}^{(2m)} \prod_{l \in E_2(\mu) \setminus j} m_{pl}^{(2s)}
\]

(212)

For the sub-matrix 1n we have:

\[
m_{\mu j}^{(1n)} = \tanh \left[ \tanh(\tilde{m}_{\mu j}^{(1n)}) + F_n \right]
\]

\[
\tilde{m}_{\mu j}^{(1n)} = J_{\mu} m_{\mu j}^{(1n)} \prod_{l \in E_1(\mu) \setminus j} m_{pl}^{(1s)}
\]

(213)

(214)

where either \( j = \mu, i = \mu + \Delta \) or \( j = \mu + \Delta, i = \mu \).

Finally, for sub-matrix 2n we have:

\[
m_{\mu}^{(2n)} = \tanh[F_n]
\]

\[
\tilde{m}_{\mu}^{(2n)} = J_{\mu} \prod_{l \in E_2(\mu)} m_{pl}^{(2s)}
\]

(215)

(216)

The pseudo-posterior and decoded message are given by:

\[
m_j = \tanh \left[ \sum_{\nu \in M_1(j)} \tanh(\tilde{m}_{\nu j}^{(1s)}) + \sum_{\nu \in M_2(j) \setminus \nu} \tanh(\tilde{m}_{\nu j}^{(2s)}) \right]
\]

\[
\xi_j = \text{sgn}(m_j).
\]

(217)

(218)

The above equations provide a microscopic description for the PP decoding process,
we can produce a macroscopic description for the typical decoding process by writing
equations for probability distributions related to the dynamical variables. It is important
to stress that the equations describing the PP decoding are entirely deterministic when
 couplings \( J_{\mu} \) and initial conditions are given. The randomness comes into the problem
when quenched averages over messages, noise and constructions are introduced.

By performing the gauge transformation

\[
m_{\mu j}^{(as)} \rightarrow \xi_j m_{\mu j}^{(as)} \quad \tilde{m}_{\nu j}^{(as)} \rightarrow \xi_j \tilde{m}_{\nu j}^{(as)}
\]

\[
m_{\mu j}^{(an)} \rightarrow \xi_j m_{\mu j}^{(an)} \quad \tilde{m}_{\nu j}^{(an)} \rightarrow \xi_j \tilde{m}_{\nu j}^{(an)}
\]

\[
J_{\mu} \rightarrow 1 \quad (a = 1, 2)
\]

(219)

(220)

(221)

introducing effective fields \( x_{\mu j} = \tanh(m_{\mu j}), \tilde{x}_{\mu j} = \tanh(\tilde{m}_{\mu j}) \) and assuming that
\( x_{\mu j}^{(as)}, x_{\mu j}^{(an)}, \tilde{x}_{\mu j}^{(as)}, \tilde{x}_{\mu j}^{(an)} \) are independently drawn from distributions \( P_a(x), \tilde{P}_a(\tilde{x}), R_a(y), \tilde{R}_a(\tilde{y}) \), respectively, we get the following saddle-point like equations (for simplicity, we
restrict the treatment to the case of unbiased messages \( F_s = 0 \)).
Figure 38. Monte-Carlo integration of field distributions and simulations for a KS code with two signal matrices $(K_1 = 1$ and $K_2 = 3)$, $\alpha = 5$ ($R = 1/5$) and $\alpha_1 = 3$. Circles: full statistics (4000 bins). Squares: simulations $N = 5000$.

For the sub-matrix 1s:

$$P_1(x) = \int \prod_{j=1}^{\alpha_1 K_1} d\hat{x}_j \hat{P}_1(x_j) \prod_{l=1}^{\alpha_1 K_2} d\hat{w}_l \hat{P}_2(\hat{w}_l) \times \delta \left[ x - \sum_{j=1}^{\alpha_1 K_1} x_j - \sum_{l=1}^{\alpha_1 K_2} w_l \right]$$  \hspace{1cm} (222)

$$\hat{P}_1(\hat{x}) = \int \prod_{j=1}^{K_1-1} dx_j P_1(x_j) dy_1 R_1(y_1) dy_2 R_1(y_2) \times \delta \left[ \hat{x} - \operatorname{atanh}(\tanh(y_1) \tanh(y_2) \prod_{j=1}^{K_1-1} \tanh(x_j)) \right]$$  \hspace{1cm} (223)

For 2s:

$$P_2(x) = \int \prod_{j=1}^{\alpha_1 K_1} d\hat{x}_j \hat{P}_1(x_j) \prod_{l=1}^{\alpha_1 K_2} d\hat{w}_l \hat{P}_2(\hat{w}_l) \times \delta \left[ x - \sum_{j=1}^{\alpha_1 K_1} x_j - \sum_{l=1}^{\alpha_1 K_2} w_l \right]$$  \hspace{1cm} (224)

$$\hat{P}_2(\hat{x}) = \int \prod_{j=1}^{K_2-1} dx_j P_2(x_j) dy R_2(y) \times \delta \left[ \hat{x} - \operatorname{atanh}(\tanh(y) \prod_{j=1}^{K_2-1} \tanh(x_j)) \right]$$
For \(1n\) we have:

\[
R_1(y) = \int d\hat{y} \hat{R}_1(\hat{y}) \langle \delta [y - \hat{y} - \zeta F_n] \rangle \xi
\]  

(226)

\[
\hat{R}_1(\hat{y}) = \prod_{j=1}^{K_1} dx_j P_j(x_j) dy R_1(y)
\]

\[
\times \delta \left[ \widehat{x} - \text{atanh}(\tanh(y) \prod_{j=1}^{K_1} \tanh(x_j)) \right]
\]

Finally, for sub-matrix \(2n\):

\[
R_2(y) = \langle \delta [y - \zeta F_n] \rangle \xi
\]  

(227)

\[
\hat{R}_2(\hat{y}) = \prod_{j=1}^{K_2} dx_j P_j(x_j) \delta \left[ \widehat{x} - \text{atanh}(\prod_{j=1}^{K_2} \tanh(x_j)) \right]
\]

The typical overlap can then be obtained as in the case of MN codes by computing:

\[
\rho = \int dh P(h) \text{sgn}(h)
\]  

(228)

\[
P(h) = \int \prod_{j=1}^{\alpha_1 K_1} d\hat{x}_j \hat{P}_1(\hat{x}_j) \prod_{l=1}^{\alpha_2 K_2} d\hat{w}_l \hat{P}_2(\hat{w}_l) \delta \left[ h - \sum_{j=1}^{\alpha_1 K_1} x_j - \sum_{l=1}^{\alpha_2 K_2} w_l \right]
\]  

(229)

The numerical solution of these equations provides the typical overlap for cascading codes with two signal matrices parameterized by \(\alpha_1 (\alpha_2 = \alpha - \alpha_1)\). In Fig.38 we compare results obtained by solving the above equations numerically (Monte-Carlo integration with 4000 bins) and PP decoding simulations (10 runs, \(N = 5000\)) with \(R = 1/5\) and \(\alpha_1 = 3\). The agreement between theory and experiments supports the assumptions employed to obtain the saddle-point like equations.

6.2. Optimizing construction parameters

Equations (222) to (229) can be used to optimize code constructions within a given family. For the family introduced in Fig.37 with fixed parameters \(K_1\) and \(K_2\) the optimization requires to find the value of \(\alpha_1\) that produces the highest threshold \(p_s\). In Fig.39 we show the threshold (spinodal noise level) \(p_s\) for a KS code with \(K_1 = 1\), \(K_2 = 3\) and rate \(R = 1/5\) (\(\alpha = 5\)). The optimal performance is obtained by selecting \(\alpha_1 = 3\) and is very close to the channel capacity.

7. Conclusions and Perspectives

In this chapter we analyzed error-correcting codes based on very sparse matrices by mapping them onto spin systems of the statistical physics. The equivalence between coding concepts and statistical physics is summarized in the following table.
Figure 39. Spinodal noise level $p_s$ as a function of $\alpha_1$ for a KS code with $K_1 = 1$, $K_2 = 3$ and $R = 1/5$ ($\alpha = 5$). Circles: Monte-Carlo integrations of saddle-point equations (4000 bins). Squares: PP decoding simulations (10 runs with size $N = 5000$). The best performance is reached for $\alpha_1 = 3$ and is close to the channel capacity for a BSC (indicated by a dashed line).

In the statistical physics framework, random parity-check matrices (or generator matrices as in the case of Sourlas codes), random messages and noise are treated as quenched disorder and the replica method is employed to compute the free-energy. Under the assumption of replica symmetry we found in most of the cases that two phases emerge: a successful decoding ($\rho = 1$) and failure ($\rho < 1$) phases. For MN codes with $K = 2$ or $K = 1$ three phases emerge representing successful decoding, failure and catastrophic failure.

The general picture that emerges shows a phase transition between successful and failure states that coincides with the information theory upper bounds in most cases, the exception being MN codes with $K = 2$ (and to some extent $K = 1$) where the transition is bellow the upper bound.

A careful analysis of replica symmetric quantities reveals unphysical behavior for low noise levels with the appearance of negative entropies. This question is resolved in
the case of Sourlas codes with $K \to \infty$ by the introduction of a simple frozen spins first-step replica symmetry breaking ansatz. Despite the difficulties in the replica symmetric analysis, threshold noise values observed in simulations using probability propagation (PP) decoding agree with the noise level where meta-stable states (or spinodal points) appear in the replica symmetric free-energy.

A mean-field (Bethe) theory based on the use of a tree-like lattice (Huimi cactus) exposes the relationship between PP decoding and statistical physics and supports the agreement between theory and simulations as PP decoding can be reinterpreted as a method for finding local minima of a Bethe free-energy. Those minima can be described by distributions of cavity local fields that are solutions of the replica symmetric saddle-point equations.

The performance of the decoding process with probability propagation can be obtained by looking at the Bethe free-energy landscape (or the replica symmetric landscape), in this way we can show that information theoretic upper bounds can be attained by looking for global minima of the Bethe free-energy, which may require computing time that grows exponentially with the system size. In practical time scales, simple decoding procedures that simply find minima become trapped in meta-stable states. That is the reason why practical thresholds are linked to the appearance of spinodal points in the Bethe free-energy.

For cascading codes we adopted a different approach for the analysis. Using the insights obtained in the analysis of the other codes we started by writing down the PP decoding equations and writing the Bethe free-energy and the saddle-point like equations for distributions of cavity fields. The transitions predicted by these saddle-point like equations were shown to agree with experiments. We then employed this procedure to optimize parameters of one simple family of cascading codes.

By studying the replica symmetric landscape we classified the various codes by their construction parameters, we also showed that modifications in code construction, like the use of irregular matrices, can improve the performance by changing the way the free-energy landscape evolves with the noise level. We summarize the results obtained in the following table:

</tbody>
</table>

These results shed light on the properties that limit the theoretical and practical performance of parity check codes, explain the differences between Gallager and MN constructions and explores the role of irregularity in LDPC error-correcting codes.

Some new directions are now being pursued and are worth mentioning. The statistical physics of Gallager codes with non-binary alphabets is investigated
in [NKS01]. In [KNS01] the performance of error-correcting codes in the case of finite message lengths has been addressed, yielding tighter general reliability bounds. New analytical methods to investigate practical noise thresholds using statistical physics have been proposed in [vMSK01] and [KvN01] while the nature of Gallager codes phase diagram was studied in detail in [Mon01].

We believe that methods developed over the years in the statistical physics community can make a significant contribution also in other areas of information theory. Research in some of these areas, such as CDMA and image restoration is already underway.

Appendix A. Sourlas Codes: Technical Details

Appendix A.1. Free-energy

In order to compute free-energies we need to calculate the replicated partition function (62). We can start from Eq.(60):

$$
\langle Z^\alpha \rangle_{A,\xi} = \text{Tr}_{\{\xi^\alpha\}} \left[ \left\langle \exp\left(-\beta \mathcal{H}(\{S^\alpha\})\right)\right\rangle_{A,\xi}\right],
$$

(A.1)

where $\mathcal{H}(\{S^\alpha\})$ represents the replicated Hamiltonian and $\alpha$ the replica indices. First we average over the parity-check tensors $A$, for that an appropriate distribution has to be introduced, denoting $\mu \equiv \{i_1, ..., i_K\}$ for a specific set of indices:

$$
\langle Z^\alpha \rangle = \left\langle \frac{1}{N} \sum_{\{A\}} \prod_i \delta \left( \sum_{\mu \setminus i} A_{\mu} - C \right) \text{Tr}_{\{\xi^\alpha\}} e^{-\beta \mathcal{H}(\{S^\alpha\})} \right\rangle_{A,\xi}
$$

(A.2)

where the $\delta$ distribution imposes a restriction on the connectivity per spin, $N$ is a normalization coefficient and the notation $\mu \setminus i$ means the set $\mu$ except the element $i$.

Using integral representations for the delta functions and rearranging:

$$
\langle Z^\alpha \rangle = \text{Tr}_{\{\xi^\alpha\}} \left\langle \frac{1}{N} \prod_i \int \frac{dZ_i}{2\pi i} \frac{1}{Z_i^{C+1}} \right\rangle_{A,\xi}
$$

A.3

$$
\times \sum_{\{A\}} \left( \prod_{\mu} \left( \prod_{i \in \mu} Z_i \right)^{A_{\mu}} \right) \exp \left(-\beta \mathcal{H}(\{S^\alpha\})\right) \right\rangle_{A,\xi}. \]

(A.3)

Remembering that $A \in \{0, 1\}$, and using the expression (50) for the Hamiltonian we can change the order of the summation and the product above and sum over $A$:

$$
\langle Z^\alpha \rangle = \text{Tr}_{\{\xi^\alpha\}} \left\langle \frac{1}{N} \prod_i \int \frac{dZ_i}{2\pi i} \frac{1}{Z_i^{C+1}} \right\rangle e^{\beta F \sum_i S_i^\alpha}
$$
\[
\times \prod_{\mu} \left[ 1 + \left( \prod_{i \in \mu} Z_i \right) \exp \left( \beta J_{\mu} \sum_{\alpha} \prod_{i \in \mu} S_i^\alpha \right) \right] \right]_{\xi}.
\] (A.4)

Using the identity \( \exp(\beta J_{\mu} \prod_{i \in \mu} S_i^\alpha) = \cosh(\beta) \left[ 1 + \left( \prod_{i \in \mu} S_i^\alpha \right) \tanh(\beta J_{\mu}) \right] \) we can perform the product over \( \alpha \) to write:

\[
\langle Z^n \rangle = \text{Tr}(S_i^{\alpha}) \frac{1}{N} \left( \prod_{i} \int \frac{dZ_i}{2 \pi i} \frac{1}{Z_i^{C+1}} \right) \left\langle e^{\beta F \sum_{\alpha,i} S_i^\alpha} \right\rangle_{\xi}
\times \prod_{\mu} \left[ 1 + \left( \prod_{i \in \mu} Z_i \right) \cosh^n(\beta) \left( 1 + \left( \tanh(\beta J) \right) J \sum_{\alpha} \prod_{i \in \mu} S_i^\alpha \right.ight.

\[
+ \left. \left( \tanh^2(\beta J) \right) J \sum_{\alpha_1 \alpha_2} \prod_{i \in \mu} Z_i S_i^{\alpha_1} S_i^{\alpha_2} + \ldots \right) \right] .
\] (A.5)

Defining \( \langle \mu_1, \mu_2, ..., \mu_l \rangle \) as an ordered set of sets, and observing that for large \( N \), 
\( \sum_{(\mu_1 \ldots \mu_l)}(...) = \frac{1}{k!} \left( \sum_{\mu}(...) \right) \) we can perform the product over the sets \( \mu \) and replace the energy series by an exponential:

\[
\langle Z^n \rangle = \text{Tr}(S_i^{\alpha}) \frac{1}{N} \left( \prod_{i} \int \frac{dZ_i}{2 \pi i} \frac{1}{Z_i^{C+1}} \right) \left\langle e^{\beta F \sum_{\alpha,i} S_i^\alpha} \right\rangle_{\xi}
\times \exp \left[ \cosh^n(\beta) \left( \sum_{\mu} \left( \prod_{i \in \mu} Z_i \right) + \langle \tanh(\beta J) \rangle J \sum_{\alpha} \sum_{\mu} \prod_{i \in \mu} z_i S_i^\alpha \right.ight.

\[
+ \left. \left( \tanh^2(\beta J) \right) J \sum_{\alpha_1 \alpha_2} \sum_{\mu} \prod_{i \in \mu} Z_i S_i^{\alpha_1} S_i^{\alpha_2} + \ldots \right) \right] .
\] (A.6)

Observing that \( \sum_{\mu} = 1/K! \sum_{k_1 \ldots k_K} \), defining \( T_k = \langle \cosh^n(\beta J) \tanh^k(\beta J) \rangle_{J} \) and introducing auxiliary variables \( q_{\alpha_1 \ldots \alpha_m} = \frac{1}{K!} \sum_{i} Z_i S_i^{\alpha_1} \ldots S_i^{\alpha_m} \) we find:

\[
\langle Z^n \rangle_{\alpha,\xi,J} = \frac{1}{N} \left( \prod_{i} \int \frac{dZ_i}{2 \pi i} \frac{1}{Z_i^{C+1}} \right) \left( \int \frac{dq_0 dq_0^*}{2 \pi i} \right)
\times \left( \prod_{\alpha} \int \frac{dq_\alpha dq_\alpha^*}{2 \pi i} \right) \ldots
\times \exp \left[ \frac{N^K}{K!} \left( T_0 q_0^K + T_1 \sum_{\alpha} q^K_{\alpha} + T_2 \sum_{(\alpha_1 \alpha_2)} q^K_{\alpha_1 \alpha_2} + \ldots \right) \right]
\times \exp \left[ -N \left( q_0 \hat{q}_0 + \sum_{\alpha} q_\alpha \hat{q}_\alpha + \sum_{(\alpha_1 \alpha_2)} q_{\alpha_1 \alpha_2} \hat{q}_{\alpha_1 \alpha_2} + \ldots \right) \right]
\times \text{Tr}(S_i^{\alpha}) \left[ \left\langle e^{\beta F \sum_{\alpha,i} S_i^\alpha} \right\rangle_{\xi} \exp \sum_{i} \left( \hat{q}_i Z_i + \sum_{\alpha} \hat{q}_\alpha Z_i S_i^\alpha + \ldots \right) \right] .
\] (A.7)
The normalization constant is given by:

$$
\mathcal{N} = \sum_{\{A\}} \prod_i \delta \left( \sum_{\mu \in A} x_i^\mu - C \right),
$$

(A.8)

and can be computed using exactly the same methods as above, resulting in:

$$
\mathcal{N} = \left( \prod_i \int \frac{dZ_i}{2\pi i Z_i^{C+1}} \right) \left( \int \frac{dq_0 dq_0^*}{2\pi i} \right) \times \exp \left[ \frac{N^K}{K!} q_0^K - N q_0 \hat{q}_0 + N \ln \left( \frac{\hat{q}_0^C}{C!} \right) \sum_i Z_i \right].
$$

(A.9)

Computing the integrals over $Z_i$'s and using Laplace method to compute the integrals over $q_0$ and $\hat{q}_0$ we obtain:

$$
\mathcal{N} = \exp \left\{ \text{Extr}_{q_0, \hat{q}_0} \left[ \frac{N^K}{K!} q_0^K - N q_0 \hat{q}_0 + N \ln \left( \frac{\hat{q}_0^C}{C!} \right) \right] \right\}.\tag{A.10}
$$

The extremum point is given by

$$
q_0 = N^{(1-K)/K} [(K-1)! C]^{1/K}
$$

and

$$
\hat{q}_0 = (C N)^{(K-1)/K} [(K-1)!]^{-1/K}.
$$

Replacing the auxiliary variables in Eq.(A.7) using $q_{\alpha_1...\alpha_m}/q_0 \rightarrow q_{\alpha_1...\alpha_m}$ and $\hat{q}_{\alpha_1...\alpha_m}/q_0 \rightarrow \hat{q}_{\alpha_1...\alpha_m}$, computing the integrals over $Z_i$ and using Laplace method to evaluate the integrals we finally find Eq.(62).

**Appendix A.2. Replica symmetric solution**

The replica symmetric free-energy (66) can be obtained by plugging the ansatz (65) into Eq.(A.7). Using Laplace method we obtain:

$$
\langle Z'' \rangle_{\xi,J} = \frac{1}{\mathcal{N}} \exp \left\{ N \text{Extr}_{\pi,\pi^*} \left[ \frac{C}{K} \mathcal{G}_1 - C \mathcal{G}_2 + \mathcal{G}_3 \right] \right\}, \tag{A.11}
$$

where:

$$
\mathcal{G}_1 = \mathcal{T}_0 + \mathcal{T}_1 \sum_{\alpha} \int \prod_j^{K} (dx_j \pi(x_j) \tanh(\beta x_j))
$$

$$
+ \mathcal{T}_2 \sum_{\langle \alpha_1, \alpha_2 \rangle} \int \prod_j^{K} (dx_j \pi(x_j) \tanh^2(\beta x_j)) + \ldots, \tag{A.12}
$$

$$
\mathcal{G}_2 = 1 + \sum_{\alpha} \int dx \int dy \pi(x) \tilde{\pi}(y) \tanh(\beta x) \tanh(\beta y)
$$

$$
+ \sum_{\langle \alpha_1, \alpha_2 \rangle} \int dx \int dy \pi(x) \tilde{\pi}(y) \tanh^2(\beta x) \tanh^2(\beta y) + \ldots \tag{A.13}
$$
\[ G_3 = \frac{1}{N} \ln \left\{ \left( \prod_i \frac{dZ_i}{2\pi i \, Z_i^{C+1}} \right) \, \text{Tr}_{\{S\}} \left[ \exp \beta F \sum_{\alpha, i} \xi_i S_i^\alpha \right] \right\} \]
\[ \times \exp \left( \sum_i Z_i + \sum_{\alpha} \sum_i Z_i S_i^\alpha \int dy \, \hat{\pi}(y) \tanh(\beta y) \right) \]
\[ + \sum_{(\alpha_1, \alpha_2)} \sum_i Z_i S_i^{\alpha_1} S_i^{\alpha_2} \int dy \, \hat{\pi}(y) \tanh^2(\beta y) + \ldots \right) \right\} \right\}. \tag{A.14} \]

The equation for \( G_i \) can be worked out by using the definition of \( T_m \) and the fact that \( (\sum_{i=1}^{C})^n = \binom{n}{i} \) to write:
\[ G_1 = \left\{ \cosh^n(\beta J) \int \left( \prod_{j=1}^{K} dx_j \pi(x_j) \right) \right. \]
\[ \times \left. \left( 1 + \tanh(\beta J) \prod_{j=1}^{K} \tanh(\beta x_j) \right)^n \right\}. \tag{A.15} \]

Following exactly the same steps we obtain:
\[ G_2 = \int dx dy \pi(x) \hat{\pi}(y) (1 + \tanh(\beta x) \tanh(\beta y))^n, \tag{A.16} \]

and
\[ G_3 = \frac{1}{N} \ln \left\{ \text{Tr}_{\{S\}} \left[ \exp \left( \beta F \sum_{\alpha} S_i^\alpha \right) \right] \right\} \]
\[ \times \int \frac{dZ}{2\pi i \, Z^{C+1}} \exp \left( \hat{q}_0 Z \int dy \, \hat{\pi}(y) \prod_{\alpha=1}^{n} (1 + S^\alpha \tanh(\beta y)) \right) \right\}. \tag{A.17} \]

Computing the integral over \( Z_i \) and the trace we finally find:
\[ G_3 = \frac{C!}{\hat{q}_0^C} \int \prod_{l=1}^{C} dy_l \hat{\pi}(y_l) \]
\[ \times \left[ \sum_{\sigma = \pm 1} \langle e^{\sigma \beta F \xi} \rangle_{\xi} \prod_{l=1}^{C} (1 + \sigma \tanh(\beta y_l)) \right] \right\}. \tag{A.18} \]

Putting everything together, using Eq.(59) and some simple manipulation we find Eq.(66).

Appendix A.3. Local field distribution

In this appendix we derive explicitly Eq.(68). The gauge transformed overlap can be written as
\[ \rho = \frac{1}{N} \sum_{i=1}^{N} \langle \text{sign}(m_i) \rangle_{A,\xi}, \tag{A.19} \]
introducing the notation $m_i = \langle S_i \rangle$, where $\langle \cdots \rangle$ is a gauged average.

For an arbitrary natural number $p$, one can compute $p$-th moment of $m_i$

$$
\langle m_i^p \rangle_{\alpha,\beta} = \lim_{n \to 0} \left\langle \sum_{S_i^1, \ldots, S_i^n} S_i^1 \cdot S_i^2 \cdot \ldots \cdot S_i^n e^{-\beta \sum_{i=1}^n \mathcal{H}^{(\alpha)}} \right\rangle_{\alpha,\beta,\xi}, \quad (A.20)
$$

where $\mathcal{H}^{(\alpha)}$ denotes the gauged Hamiltonian of the $\alpha$-th replica. By performing the same steps described in the Appendices Appendix A.1 and Appendix A.2, introducing the auxiliary functions $\pi(x)$ and $\hat{\pi}(y)$ defined in Eqs.(65), one obtains

$$
\langle m_i^p \rangle_{\alpha,\beta} = \int \prod_{j=1}^C dy_j \hat{\pi}(y_j) \left\langle \tanh^p \left( \beta F \xi + \beta \sum_{j=1}^C y_j \right) \right\rangle_{\xi}, \quad (A.21)
$$

Employing the identity

$$
\text{sign}(x) + 1 = 2 \lim_{n \to \infty} \sum_{m=0}^n \frac{2n!}{(2n-m)!m!} \left( \frac{1+x}{2} \right)^{2n-m} \left( \frac{1-x}{2} \right)^m \quad (A.22)
$$

which holds for any arbitrary real number $x \in [-1,1]$ and Eqs.(A.21) and (A.22) one obtains

$$
\langle \text{sign}(m_i) \rangle_{\alpha,\beta} + 1 = 2 \int dh \ P(h) \left( \frac{1+h}{2} \right)^{2n-m} \left( \frac{1-h}{2} \right)^m \quad (A.23)
$$

where we introduced the local fields distribution

$$
P(h) = \int \prod_{j=1}^C dy_j \ \hat{\pi}(y_j) \left\langle \delta(h - F \xi - \sum_{j=1}^C y_j) \right\rangle_{\xi}, \quad (A.24)
$$

thus reproducing Eq.(68).

Appendix A.4. Zero temperature self-consistent equations

In this appendix we describe how one can write a set of self-consistent equations to solve the zero temperature saddle-point equations (84). Supposing a three peaks ansatz given by:

$$
\hat{\pi}(y) = p_+ \delta(y-1) + p_0 \delta(y) + p_- \delta(y+1) \quad (A.25)
$$

$$
\pi(x) = \sum_{l=-C}^{C-1} T_{[p_+,p_0,p_-;C,C]}(l) \delta(x-l), \quad (A.26)
$$

with

$$
T_{[p_+,p_0,p_-;C,C]}(l) = \sum_{\{k,h,m : k-h=l \ ; k+h+m=C-1\}} \frac{(C-1)!}{k! \ h! \ m!} p_+^k \ p_0^h \ p_-^m. \quad (A.27)
$$
We can consider the problem as a random walk, where $\hat{\pi}(y)$ describes the probability of one step of length $y$ ($y > 0$ means one step to the right) and $\pi(x)$ describes the probability of being at distance $x$ from the origin after $C - 1$ steps. With this idea in mind it is relatively easy to understand $T_{p_+, p_0, p_-; C-1}(l)$ as the probability of walking the distance $l$ after $C - 1$ steps with the probabilities $p_+$, $p_-$ and $p_0$ of respectively moving right, left and staying at the same position. We define the probabilities of walking right/left as $\psi_\pm = \sum_{l=1}^{C-1} T_{p_+, p_0, p_-; C-1}(\pm l)$. Using second saddle-point equations (84):

\[
p_+ = \int \left[ \prod_{l=1}^{K-1} dx_l \pi(x_l) \right] \times \left[ \delta \left[ 1 - \text{sign}(J \prod_{l=1}^{K-1} x_l) \min(|J|, |x_1|, \ldots) \right] \right]_J.
\]

The right side of the above equality can be read as the probability of making $K - 1$ independent walks, such that after $C - 1$ steps: none is at origin and an even (for $J = +1$) or odd (for $J = -1$) number of walks is at the left side.

Using this reasoning for $p_-$ and $p_0$ we can finally write:

\[
p_+ = (1 - p) \sum_{j=0}^{\left[ \frac{K-1}{2} \right]} \frac{(K - 1)!}{2j!(K - 1 - 2j)!} \psi_-^{2j} \psi_+^{K-2j-1}
\]

\[
+ p \sum_{j=0}^{\left[ \frac{K-1}{2} \right]} \frac{(K - 1)!}{(2j + 1)!(K - 2 - 2j)!} \psi_-^{2j+1} \psi_+^{K-2j-2}
\]

\[
+ p \psi_-^{K-1} \text{odd}(K - 1)
\]

\[
p_- = (1 - p) \sum_{j=0}^{\left[ \frac{K-1}{2} \right]} \frac{(K - 1)!}{(K - 2j - 1)!(2j + 1)!} \psi_-^{2j} \psi_+^{K-2j-2}
\]

\[
+ p \sum_{j=0}^{\left[ \frac{K-1}{2} \right]} \frac{(K - 1)!}{(K - 2j - 1)!(2j)!} \psi_-^{2j+1} \psi_+^{K-2j-1}
\]

\[
+ (1 - p) \psi_-^{K-1} \text{odd}(K - 1),
\]

where odd$(x) = 1(0)$ if $x$ is odd (even). Using that $p_+ + p_- + p_0 = 1$ one can obtain $p_0$. A similar set of equations can be obtained for a five peaks ansatz leading to the same set of solutions for the ferromagnetic and paramagnetic phases. The paramagnetic solution $p_0 = 1$ is always a solution, for $C > K$ a ferromagnetic solution with $p_+ > p_- > 0$ emerges.
Appendix A.5. \( \langle J \rangle_J = \langle J \tanh(\beta N J) \rangle_J \)

In this appendix we establish the identity \( \langle J \rangle_J = \langle J \tanh(\beta N J) \rangle_J \) for symmetric channels. It was shown in [Sou94a] that:

\[
\beta N J \frac{1}{2} \ln \left( \frac{p(J \mid 1)}{p(J \mid -1)} \right),
\]

where \( \beta N \) is the Nishimori temperature and \( p(J \mid J^0) \) are the probabilities that a transmitted bit \( J^0 \) is received as \( J \). From this we can easily find:

\[
\tanh (\beta N J) = \frac{p(J \mid 1) - p(J \mid -1)}{p(J \mid 1) + p(J \mid -1)}.
\]

In a symmetric channel \( p(J \mid -J^0) = p(-J \mid J^0) \), it is also represented as

\[
\tanh (\beta N J) = \frac{p(J \mid 1) - p(-J \mid 1)}{p(J \mid 1) + p(-J \mid 1)}.
\]

Therefore,

\[
\langle J \tanh (\beta N J) \rangle_J = \text{Tr}_J p(J \mid 1) \frac{J p(J \mid 1)}{p(J \mid 1) + p(-J \mid 1)}
\]

\[
+ \text{Tr}_J p(J \mid 1) \frac{(-J) p(-J \mid 1)}{p(J \mid 1) + p(-J \mid 1)}
\]

\[
= \text{Tr}_J p(J \mid 1) \frac{J p(J \mid 1)}{p(J \mid 1) + p(-J \mid 1)}
\]

\[
+ \text{Tr}_J p(-J \mid 1) \frac{J p(J \mid 1)}{p(-J \mid 1) + p(J \mid 1)}
\]

\[
= \text{Tr}_J J p(J \mid 1)
\]

\[
= \langle J \rangle_J.
\]

Appendix A.6. Probability propagation equations

In this section we derive the probability propagation equations (36) and (34) in the form (96). We start by introducing the following representation for the variables \( Q_{\mu k}^S \) and \( R_{\mu k}^S \):

\[
Q_{\mu k}^S = \frac{1}{2}(1 + m_{\mu k} S_k), \quad R_{\mu k}^S = \frac{1}{2}(1 + \hat{m}_{\mu k} S_k).
\]

We can now put (91), (95) and (A.35) together to write:

\[
R_{\mu j}^S = \frac{1}{d_{\mu}} \sum_{\{S_{j k} \in \mathcal{L}(\mu) \mid j\}} \frac{1}{2} \cosh(\beta J_{\mu}) \left( 1 + \tanh(\beta J_{\mu}) \prod_{j \in \mathcal{L}(\mu)} S_j \right)
\]

\[
\times \prod_{k \in \mathcal{L}(\mu) \mid j} \frac{1}{2} (1 + m_{\mu k} S_k)
\]

\[
= \frac{1}{2^R} \frac{1}{d_{\mu}} \sum_{\{S_{j k} \in \mathcal{L}(\mu) \mid j\}} \cosh(\beta J_{\mu}) \left( 1 + \tanh(\beta J_{\mu}) \prod_{j \in \mathcal{L}(\mu)} S_j \right)
\]

\[
= \frac{1}{2^R} \frac{1}{d_{\mu}} \sum_{\{S_{j k} \in \mathcal{L}(\mu) \mid j\}} \cosh(\beta J_{\mu}) \left( 1 + \tanh(\beta J_{\mu}) \prod_{j \in \mathcal{L}(\mu)} S_j \right)
\]

\[
= \frac{1}{2^R} \frac{1}{d_{\mu}} \sum_{\{S_{j k} \in \mathcal{L}(\mu) \mid j\}} \cosh(\beta J_{\mu}) \left( 1 + \tanh(\beta J_{\mu}) \prod_{j \in \mathcal{L}(\mu)} S_j \right)
\]
\[
\times \left( 1 + \sum_{k \in \mathcal{L}(\mu)\setminus j} m_{\mu k} S_k + \sum_{k \notin \mathcal{L}(\mu)\setminus j} m_{\mu k} m_{\mu k} S_k S_j + \cdots \right)
\]

\[
= \frac{1}{2K} a_{\mu} \cosh(\beta J_\mu) \left( 1 + \tanh(\beta J_\mu) S_j \prod_{k \in \mathcal{L}(\mu)\setminus j} m_{\mu k} \right)
\]

\[
= \frac{1}{2} \left( 1 + \tanh(\beta J_\mu) S_j \prod_{k \in \mathcal{L}(\mu)\setminus j} m_{\mu k} \right).
\]

(A.36)

To obtain the last line we used that the normalization constant is \(a_{\mu} = \frac{1}{2K} \cosh(\beta J_\mu)\).

Writing the above equation in terms of the new variable \(\hat{m}_{\mu k}\) we obtain the first equation (96):

\[
\hat{m}_{\mu k} = R_{\mu k}^{(+)} - R_{\mu k}^{(-)}
\]

\[
= \frac{1}{2} \left( 1 + \tanh(\beta J_\mu) \prod_{k \in \mathcal{L}(\mu)\setminus j} m_{\mu k} \right)
\]

\[
- \frac{1}{2} \left( 1 - \tanh(\beta J_\mu) \prod_{k \in \mathcal{L}(\mu)\setminus j} m_{\mu k} \right)
\]

\[
= \tanh(\beta J_\mu) \prod_{k \in \mathcal{L}(\mu)\setminus j} m_{\mu k}.
\]

(A.37)

To obtain the second equation (96), we write:

\[
Q_{\mu k}^{s_k} = a_{\mu k} \frac{1}{2} \left( 1 + \tanh(\beta_{\mu} S_k) \right) \prod_{\nu \in \mathcal{M}(k) \setminus \mu} \frac{1}{2} \left( 1 + \hat{m}_{\nu k} S_k \right).
\]

(A.38)

In the new variables \(m_{\mu k}\):

\[
m_{\mu k} = a_{\mu k} \frac{1}{2K} \left\{ (1 + \tanh(\beta_{\mu}')) \prod_{\nu \in \mathcal{M}(k) \setminus \mu} (1 + \hat{m}_{\nu k}) \right\}
\]

\[
- (1 - \tanh(\beta_{\mu}')) \prod_{\nu \in \mathcal{M}(k) \setminus \mu} (1 - \hat{m}_{\nu k}) \}
\]

(A.39)

By using the identity \(e^{w} = \cosh(x)(1 + \sigma \tanh(x))\) we can write:

\[
m_{\mu k} = \frac{a_{\mu k}^{-1} 2K}{\cosh(\beta_{\mu}') \prod_{\nu \in \mathcal{M}(k) \setminus \mu} \cosh(\tanh(m_{\nu k}))}
\]

\[
\exp \left[ \sum_{\nu \in \mathcal{M}(k) \setminus \mu} \tanh(m_{\nu k}) + \beta_{\mu}' \right]
\]

\[- \frac{a_{\mu k}^{-1} 2K}{\cosh(\beta_{\mu}') \prod_{\nu \in \mathcal{M}(k) \setminus \mu} \cosh(\tanh(m_{\nu k}))}
\]

\[
\exp \left[ - \sum_{\nu \in \mathcal{M}(k) \setminus \mu} \tanh(m_{\nu k}) - \beta_{\mu}' \right]
\]

(A.40)

Computing the normalization \(a_{\mu j}\) along the same lines gives:

\[
a_{\mu k}^{-1} = \frac{\exp \left[ \sum_{\nu \in \mathcal{M}(k) \setminus \mu} \tanh(m_{\nu k}) + \beta_{\mu}' \right]}{2K \cosh(\beta_{\mu}') \prod_{\nu \in \mathcal{M}(k) \setminus \mu} \cosh(\tanh(m_{\nu k}))}
\]
\[
\frac{1}{2^K} \exp \left[ -\sum_{\nu \in \mathcal{M}(k)} \tanh(m_{\nu k}) - \beta_N' \right] 
\]

Inserting (A.41) into (A.40) gives:

\[
m_{\nu k} = \tanh \left[ \sum_{\nu \in \mathcal{M}(k)} \tanh(m_{\nu k}) + \beta_N' \right].
\]

### Appendix B. Gallager Codes: Technical Details

#### Appendix B.1. Replica theory

The replica theory for Gallager codes is very similar to the theory obtained for Sourlas codes (see Appendix A). We start with Eq. (116):

\[
\langle Z^n \rangle_\mathcal{A} = \sum_{\tau_1, \ldots, \tau_n} \prod_{j=1}^M \left\langle \exp \left( F \zeta \beta \sum_{\alpha=1}^n \tau_{j \alpha}^a \right) \right\rangle_{\zeta} 
\]

\[
\times \left\langle \prod_{(i_1 \ldots i_K)} \prod_{\alpha=1}^n \exp \left[ \beta \gamma A_{(i_1 \ldots i_K)} (\tau_{i_1}^a \cdots \tau_{i_K}^a - 1) \right] \right\rangle_{\mathcal{A}}.
\]

The average over constructions \( \mathcal{A} \) is then introduced using Eq. (117):

\[
\langle Z^n \rangle_\mathcal{A} = \frac{1}{\mathcal{N}} \sum_{\tau_1, \ldots, \tau_n} \prod_{j=1}^M \left\langle \exp \left( F \zeta \beta \sum_{\alpha=1}^n \tau_{j \alpha}^a \right) \right\rangle_{\zeta} 
\]

\[
\times \prod_{(i_1 \ldots i_K)} \prod_{\alpha=1}^n \exp \left[ \beta \gamma A_{(i_1 \ldots i_K)} (\tau_{i_1}^a \cdots \tau_{i_K}^a - 1) \right].
\]

After observing that

\[
\prod_{j=1}^M Z_j^{\sum_{(i_1 \ldots i_K)} A_{(i_1 \ldots i_K)} = \prod_{(i_1 \ldots i_K)} (Z_{i_1} \cdots Z_{i_K})_{A_{(i_1 \ldots i_K)}},}
\]

we can compute the sum over \( \mathcal{A}_{(i_1 \ldots i_K)} \in \{0, 1\}:

\[
\langle Z^n \rangle_\mathcal{A}_{\zeta} = \frac{1}{\mathcal{N}} \sum_{\tau_1, \ldots, \tau_n} \prod_{j=1}^M \left\langle \exp \left( F \zeta \beta \sum_{\alpha=1}^n \tau_{j \alpha}^a \right) \right\rangle_{\zeta} 
\]

\[
\times \prod_{j=1}^M \left[ \phi \frac{dZ_j}{Z_j^{C+1}} \right] 
\]

\[
\times \prod_{(i_1 \ldots i_K)} \left\{ 1 + \frac{Z_{i_1} \cdots Z_{i_K}}{\epsilon^a \beta \gamma} \sum_{\alpha=1}^n \exp \left[ \beta \gamma (\tau_{i_1}^a \cdots \tau_{i_K}^a) \right] \right\}.
\]
We can now use the identity $e^x = \cosh(x)(1 + \sigma \tanh(x))$, where $\sigma = \pm 1$, to write:

\[
\langle Z^n \rangle_{A, \zeta} = \frac{1}{N} \sum_{\tau_1, \ldots, \tau_n} \prod_{j=1}^{M} \left\langle \exp \left( F \zeta \sum_{\alpha=1}^{n} \tau_{\alpha}^{j} \right) \right\rangle_{\zeta} 
\times \sum_{\{A\}} \prod_{j=1}^{M} \left[ \int \frac{dZ_{j}}{2\pi i} \frac{1}{Z_{j}^{C+1}} \right] 
\times \prod_{(i_{1} \ldots i_{K})} \left\{ 1 + \frac{\cosh^{n} (\beta \gamma)}{\cosh (\beta \gamma)} (Z_{i_{1}} \cdots Z_{i_{K}}) \right\} 
\times \prod_{\alpha=1}^{n} \left[ 1 + \tau_{i_{1}}^{\alpha} \cdots \tau_{i_{K}}^{\alpha} \tanh (\beta \gamma) \right] \right\}.
\]

By following Appendix A.1 from Eq.(A.5) we can finally find Eq.(120).

**Appendix B.2. Replica symmetric solution**

As in the code of Sourlas (Appendix A.2) the replicated partition function can be put into the form:

\[
\langle Z^n \rangle_{A, \zeta} = \frac{1}{N} \exp \left\{ M \text{ Exr}_{n, \tilde{\sigma}} \left[ \frac{C}{K} \mathcal{G}_{1} - C \mathcal{G}_{2} + \mathcal{G}_{3} \right] \right\}.
\]

Introducing the replica symmetric ansatz (121) into the functions $\mathcal{G}_{1}$, $\mathcal{G}_{2}$ and $\mathcal{G}_{3}$ we obtain:

\[
\mathcal{G}_{1}(n) = \mathcal{T}_{0} + \mathcal{T}_{1} \sum_{\alpha} q_{\alpha}^{K} + \mathcal{T}_{2} \sum_{(\alpha \alpha \beta)} q_{\alpha \alpha \beta}^{K} + \cdots
\]

\[
= \frac{\cosh^{n} (\beta \gamma)}{\cosh (\beta \gamma)} \int \prod_{j=1}^{K} dx_{j} \pi (x_{j}) \left[ 1 + \frac{n!}{(n-1)!} \tanh (\beta \gamma) \prod_{j=1}^{K} x_{j} \right]
\]

\[
+ \frac{n!}{(n-2)!} \tanh^{2} (\beta \gamma) \prod_{j=1}^{K} x_{j}^{2} + \cdots
\]

\[
= \frac{\cosh^{n} (\beta \gamma)}{\cosh (\beta \gamma)} \int \prod_{j=1}^{K} dx_{j} \pi (x_{j}) \left[ 1 + \tanh (\beta \gamma) \prod_{j=1}^{K} x_{j} \right]^{\gamma}
\]

\[
\gamma \rightarrow \infty \quad \frac{1}{2^n} \int \prod_{j=1}^{K} dx_{j} \pi (x_{j}) \left[ 1 + \prod_{j=1}^{K} x_{j} \right]^{n},
\]

where we use the Nishimori condition $\gamma \rightarrow \infty$, $\beta = 1$ to obtain the last line.

\[
\mathcal{G}_{2}(n) = 1 + \sum_{\alpha} q_{\alpha} \hat{q}_{\alpha} + \sum_{(\alpha \alpha \beta)} q_{\alpha \alpha \beta} \hat{q}_{\alpha \alpha \beta} + \cdots
\]

\[
= \int dx d\hat{x} \pi (x) \hat{\pi} (\hat{x}) [1 + x \hat{x}]^{n}.
\]

\[
\mathcal{G}_{3}(n) = \frac{1}{M} \ln \text{Tr}_{\{n\}} \left\langle \exp \left[ F \beta \zeta \sum_{\alpha=1}^{n} \tau_{\alpha}^{\alpha} \right] \right\rangle_{\zeta}
\]
\begin{align}
&\times \oint \frac{dZ}{2\pi i} \exp \left[ \frac{Z \sum_{m=0}^{n} \sum_{\alpha_1 \cdots \alpha_m} \hat{q}_{\alpha_1 \cdots \alpha_m} \tau^{\alpha_1} \cdots \tau^{\alpha_m}}{Z^{c+1}} \right] \\
&= \frac{1}{M} \ln \Tr_{\{\tau\}^c} \left[ \exp \left( F \beta \zeta \sum_{\alpha=1}^{n} \tau^\alpha \right) \right] \\
&\times \oint \frac{dZ}{2\pi i} \exp \left( \int \frac{d\hat{\tau}(\hat{x})}{Z^{c+1}} \prod_{\alpha=1}^{n} (1 + \tau^\alpha \hat{x}) \right) \\
&= \frac{1}{M} \ln \left( \frac{q^c}{c^i} \right) \int d\hat{\tau}_1 \frac{\hat{\tau}(\hat{x}_1)}{C} \sum_{\tau=\pm1} \left( e^{F \beta \zeta \tau} \right)^c \prod_{l=1}^{C} (1 + \tau \hat{\tau}_l) \right]^{n} \tag{B.8}
\end{align}

By using Eq.(115) we can write

\begin{align}
f = -\frac{1}{\beta} \text{Extr}_{\tau, \hat{x}} \frac{\partial}{\partial n} \left[ \frac{C}{K} \mathcal{G}_1(n) - C \mathcal{G}_2(n) + \mathcal{G}_3(n) \right], \tag{B.9}
\end{align}

what yields the free-energy (123).

Appendix B.3. Energy density at the Nishimori condition

In general the average internal energy is evaluated as:

\begin{align}
U &= \langle \mathcal{H}(\gamma^*, F^*) \rangle_{\beta, \xi} \tag{B.10} \\
&= \sum_{\mathcal{J}} \frac{\sum_{\zeta} \mathcal{P}_{\gamma^*}(\{\mathcal{J}_\mu\} | \zeta) \mathcal{P}_{\beta}(\zeta)}{\sum_{\mathcal{J}, \zeta} \mathcal{P}_{\gamma^*}(\{\mathcal{J}_\mu\} | \zeta) \mathcal{P}_{\beta}(\zeta)} \\
&\times \frac{\sum_{\mathcal{J}} \mathcal{H}(\gamma^*, F^*) \mathcal{P}_{\gamma^*}(\{\mathcal{J}_\mu\} | \tau) \mathcal{P}_{\beta}(\tau)}{\sum_{\mathcal{J}} \mathcal{P}_{\gamma^*}(\{\mathcal{J}_\mu\} | \tau) \mathcal{P}_{\beta}(\tau)}, \tag{B.11}
\end{align}

where the hyper-parameters \( \gamma^*, F^* \) are used in the Hamiltonian \( \mathcal{H} \) and \( \beta^* \) is the temperature, while \( \gamma, F, \) and \( \beta \) are the actual parameters of the encoding and corruption processes.

The Nishimori condition is defined by setting the temperature and all hyper-parameters of the Hamiltonian to the values in the encoding and corruption processes. If this is done, the expression for the energy can be rewritten:

\begin{align}
U &= \frac{\sum_{\mathcal{J}, \tau} \mathcal{H}(\gamma, F) \mathcal{P}_{\gamma}(\{\mathcal{J}_\mu\} | \tau) \mathcal{P}_{\beta}(\tau)}{\sum_{\mathcal{J}, \tau} \mathcal{P}_{\gamma}(\{\mathcal{J}_\mu\} | \tau) \mathcal{P}_{\beta}(\tau)}. \tag{B.12}
\end{align}

By plugging (106) for the likelihood \( \mathcal{P}_{\gamma}(\{\mathcal{J}_\mu\} | \tau) \) and for the prior \( \mathcal{P}_{\beta}(\zeta) \); setting the hyperparameters to \( \gamma \rightarrow \infty, \beta = 1 \) and \( F = \text{atanh}(1 - 2p) \) and performing the summation over \( \mathcal{J} \) first, we easily get:

\begin{align}
u = \lim_{M \rightarrow \infty} \frac{U}{M} = - F (1 - 2p). \tag{B.13}
\end{align}

Note that this expression is independent of the macroscopic state of the system.
Appendix B.4. Recursion relations

We start by introducing the effective field $\hat{x}_{\nu j}$:

$$\tanh(\beta \hat{x}_{\nu j}) = \frac{P_{\nu j}(+)-e^{-\beta F} - P_{\nu j}(-)e^{+\beta F}}{P_{\nu j}(+)-e^{-\beta F} + P_{\nu j}(-)e^{+\beta F}}. \tag{B.14}$$

Equation (129) can be easily obtained from the equation above. Equation (130) is then obtained by introducing Eq.(128) into Eq.(129) and performing a straightforward manipulation we obtain Eq.(131):

$$\exp(-2\beta \hat{x}_{\mu k}) = \frac{\text{Tr}_{\{\tau_j\}} \prod_j e^{\beta \gamma (\tilde{\mathcal{J}_\mu} \prod_j \tau_j - 1)} \prod_a \prod_j e^{\beta F \tau_a + \beta \hat{x}_{\nu j} (\tau_j - 1)}}{\text{Tr}_{\{\tau_j\}} \prod_j e^{\beta \gamma (\tilde{\mathcal{J}_\mu} \prod_j \tau_j - 1)} \prod_a \prod_j e^{\beta F \tau_a + \beta \hat{x}_{\nu j} (\tau_j - 1)}}, \tag{B.15}$$

where

$$\exp(\beta \hat{x}_{\nu j}(\tau_j - 1)) = \frac{P_{\nu j} (\tau_j)e^{-\beta F \tau_j}}{P_{\nu j} (+)e^{-\beta F}}$$

and the products $\prod_j$ and $\prod_a$ are over $\nu \in \mathcal{M}(j) \setminus \mu$ and $j \in \mathcal{L}(\mu) \setminus k$ respectively.

The above equation can be rewritten as:

$$e^{-2\beta \hat{x}_{\mu k}} = \frac{\text{Tr}_{\{\tau_j\}} \prod_j e^{\beta F + \sum_j \hat{x}_{\nu j}} \tau_j \left[ \left( 1 - \tilde{\mathcal{J}_\mu} \prod_j \tau_j \tanh(\beta \gamma) \right) \right]}{\text{Tr}_{\{\tau_j\}} \prod_j e^{\beta F + \sum_j \hat{x}_{\nu j}} \tau_j \left[ \left( 1 + \tilde{\mathcal{J}_\mu} \prod_j \tau_j \tanh(\beta \gamma) \right) \right]}. \tag{B.16}$$

By introducing the Nishimori condition $\beta = 1$ and $\gamma \to \infty$ and computing traces:

$$\exp(-2\beta \hat{x}_{\mu k}) = \prod_{j \in \mathcal{L}(\mu) \setminus k} \sum_{\tau = \pm 1} \mathcal{E}^{\nu_{j\tau}} - \tilde{\mathcal{J}_\mu} \prod_{j \in \mathcal{L}(\mu) \setminus k} \sum_{\tau = \pm 1} \mathcal{E}^{\nu_{j\tau}}$$

$$= \frac{1 - \tilde{\mathcal{J}_\mu} \prod_{j \in \mathcal{L}(\mu) \setminus k} \tanh(\hat{x}_{\nu j})}{1 + \tilde{\mathcal{J}_\mu} \prod_{j \in \mathcal{L}(\mu) \setminus k} \tanh(\hat{x}_{\nu j})}, \tag{B.17}$$

where we have introduced

$$x_{\nu j} = F + \sum_{\nu \in \mathcal{M}(j) \setminus \mu} \hat{x}_{\nu j}.$$

A brief manipulation of the equation above yields Eq.(131).

Appendix C. MN codes: technical details

Appendix C.1. Distribution of syndrome bits

In this section we evaluate probabilities $p_\mu$ associated to syndrome bits in MN and Gallager codes.

In the case of Gallager codes a syndrome bit $\mu$ has the form

$$z_\mu = \zeta_1 \oplus \cdots \oplus \zeta_k, \tag{C.1}$$

where $\zeta \in \{0,1\}$ and $\oplus$ denotes mod 2 sums. Each bit $\zeta$ is randomly drawn with probabilities $P(\zeta = 1) = p$ and $P(\zeta = 0) = 1 - p$. The probability $p_\mu(K)$ of $z_\mu = 0$
equates with the probability of having an even number of $\zeta = 1$ in the summation, therefore:

$$p^0_z(K) = \sum_{t \text{ even}}^K \frac{K!}{(K - t)!!} p^t (1 - p)^{K - t}$$

$$= \sum_{t \text{ even}}^K (-1)^t \frac{K!}{(K - t)!!} p^t (1 - p)^{K - t}. \quad \text{(C.2)}$$

Consequently

$$p^1_z(K) = \sum_{t \text{ odd}}^K \frac{K!}{(K - t)!!} p^t (1 - p)^{K - t}$$

$$= -\sum_{t \text{ odd}}^K (-1)^t \frac{K!}{(K - t)!!} p^t (1 - p)^{K - t}. \quad \text{(C.3)}$$

From equations (C.2) and (C.3) above we can write:

$$1 - 2p^1_z(K) = \sum_{t \text{ odd}}^K (-1)^t \frac{K!}{(K - t)!!} p^t (1 - p)^{K - t}$$

$$= (1 - p - p)^K = (1 - 2p)^K. \quad \text{(C.4)}$$

From what we find:

$$p^1_z(K) = \frac{1}{2} - \frac{1}{2} (1 - 2p)^K. \quad \text{(C.5)}$$

For MN codes syndrome bits have the form:

$$z_\mu = \xi_{j_1} + \cdots + \xi_{j_K} \oplus \zeta_1 \oplus \cdots \oplus \zeta_L, \quad \text{(C.6)}$$

where signal bits $\xi_j$ are randomly drawn with probability $P(\xi = 1) = p_\xi$ and noise bits $\zeta$ are drawn with probability $P(\zeta = 1) = p$.

The probability $p^0_z(K, L)$ of $z_\mu = 0$ is, therefore:

$$p^0_z(K, L) = p^0_z(K)p^0_z(L) + p^1_z(K)p^1_z(L)$$

$$= 1 - p^1_z(K) - p^1_z(L) + 2p^1_z(K)p^1_z(L). \quad \text{(C.7)}$$

where $p^0_z(K)$ and $p^0_z(L)$ stand for probabilities involving the $K$ signal bits and $L$ noise bits, respectively.

By plugging equation (C.5) into equation (C.7) we get:

$$p^1_z(K, L) = 1 - p^0_z(K, L)$$

$$= \frac{1}{2} - \frac{1}{2} (1 - 2p_\xi)^K (1 - 2p)^L. \quad \text{(C.8)}$$
Appendix C.2. Replica theory

For MN codes the replicated partition function has the following form:

\[
\langle Z^n \rangle_{A, \xi, \zeta} = \sum_{S^1, \ldots, S^n} \sum_{\tau^1, \ldots, \tau^n} \prod_{j=1}^{n} \left( \exp \left( F_s \xi \beta \sum_{\alpha=1}^{n} S^\alpha_j \right) \right)_{\xi} \\
\times \prod_{l=1}^{M} \left( \exp \left( F_n \zeta \beta \sum_{\alpha=1}^{n} \tau^\alpha_l \right) \right)_{\zeta} \\
\times \left\langle \prod_{\langle jl \rangle} \prod_{\alpha=1}^{n} \exp \left[ \beta \gamma A_{jl_1 j_1} (S^\alpha_{j_1} \cdots S^\alpha_{j_L} \tau^\alpha_{l_1} \cdots \tau^\alpha_{l_L} - 1) \right] \right\rangle_{A} .
\] (C.9)

By introducing averages over constructions (117) as described in Appendix B.1 we find:

\[
\langle Z^n \rangle_{A, \xi, \zeta} = \sum_{S^1, \ldots, S^n} \sum_{\tau^1, \ldots, \tau^n} \prod_{j=1}^{n} \left( \exp \left( F_s \xi \beta \sum_{\alpha=1}^{n} S^\alpha_j \right) \right)_{\xi} \\
\times \prod_{j=1}^{M} \left( \exp \left( F_n \zeta \beta \sum_{\alpha=1}^{n} \tau^\alpha_j \right) \right)_{\zeta} \\
\times \sum_{\{C_j, D_l\}} \prod_{j=1}^{N} P_C(C_j) \prod_{l=1}^{M} P_D(D_l) \\
\times \frac{1}{N} \sum_{\{A\}} \prod_{j=1}^{N} \left[ \oint \frac{dZ_j}{2\pi i} \frac{1}{Z_j^{c_j+1}} \right] \\
\times \prod_{l=1}^{M} \left[ \oint \frac{dY_l}{2\pi i} Y_l^{D_l+1} \right] \\
\times \prod_{\langle jl \rangle} \exp \left[ \beta \gamma A_{jl_1 j_1} (S^\alpha_{j_1} \cdots S^\alpha_{j_L} \tau^\alpha_{l_1} \cdots \tau^\alpha_{l_L} - 1) \right] .
\] (C.10)

Computing the sum over \( A \) we get:

\[
\langle Z^n \rangle_{A, \xi, \zeta} = \sum_{S^1, \ldots, S^n} \sum_{\tau^1, \ldots, \tau^n} \prod_{j=1}^{n} \left( \exp \left( F_s \xi \beta \sum_{\alpha=1}^{n} S^\alpha_j \right) \right)_{\xi} \\
\times \prod_{j=1}^{M} \left( \exp \left( F_n \zeta \beta \sum_{\alpha=1}^{n} \tau^\alpha_j \right) \right)_{\zeta} \\
\times \sum_{\{C_j, D_l\}} \prod_{j=1}^{N} P_C(C_j) \prod_{l=1}^{M} P_D(D_l) \frac{1}{N} \\
\times \oint \frac{dZ_j}{2\pi i} Z_j^{c_j+1} \oint \frac{dY_l}{2\pi i} Y_l^{D_l+1} \\
\times \prod_{\langle jl \rangle} \left\{ 1 + \frac{Z_{i_1} \cdots Z_{i_k} Y_{i_1} \cdots Y_{i_L}}{e^{n \beta r}} \right\} .
\]
\begin{equation}
\times \prod_{\alpha=1}^{n} \exp \left[ \beta \gamma (S_{i_1}^{\alpha} \cdots S_{i_k}^{\alpha} \tau_{1_1}^{\alpha} \cdots \tau_{l_1}^{\alpha}) \right] \right \}.
\end{equation}

We use the identity \( e^{\sigma} = \cosh(\sigma)(1 + \sigma \tanh(\sigma)) \), where \( \sigma = \pm 1 \), to write:

\begin{equation}
\langle Z^n \rangle_{A, \xi, \zeta} = \sum_{S_{i_1}^{\alpha}, \ldots, S_{i_K}^{\alpha}} \sum_{\tau_{1_1}^{\alpha}, \ldots, \tau_{l_1}^{\alpha}} \prod_{j=1}^{M} \left( \exp \left( F_{j} \xi \beta \sum_{\alpha=1}^{n} S_{j}^{\alpha} \right) \right)_{\xi} \prod_{j=1}^{M} \left( \exp \left( F_{n} \zeta \beta \sum_{\alpha=1}^{n} \tau_{j}^{\alpha} \right) \right)_{\zeta} \\
\times \sum_{\{C_j, D_k\}} \prod_{j=1}^{N} P_{C}(C_j) \prod_{l=1}^{M} P_{D}(D_l) \\
\times \frac{1}{N} \int \frac{d\bar{Z}_{j}}{2\pi i} \frac{1}{Z_{j}^{C_j+1}} \int \frac{d\bar{Y}_{l}}{2\pi i} \frac{1}{Y_{l}^{D_l+1}} \\
\times \prod_{(i\ell)} \left\{ 1 + \frac{\cosh^n(\beta \gamma)}{e^{n\beta \gamma}} (Z_{i_1}^{\alpha_1} \cdots Z_{i_k}^{\alpha_m} Y_{1_1}^{\alpha_1} \cdots Y_{l_1}^{\alpha_m}) \right\}.
\end{equation}

The product in the replica index \( \alpha \) yields:

\begin{equation}
\prod_{\alpha=1}^{n} \left[ 1 + S_{i_1}^{\alpha} \cdots S_{i_k}^{\alpha} \tau_{1_1}^{\alpha} \cdots \tau_{l_1}^{\alpha} \tanh(\beta \gamma) \right] = \sum_{m=0}^{n} \left[ \tanh^{m}(\beta \gamma) \right]
\end{equation}

\begin{equation}
\times \sum_{\langle \alpha_1, \ldots, \alpha_m \rangle} S_{i_1}^{\alpha_1} \cdots S_{i_k}^{\alpha_m} \tau_{1_1}^{\alpha_1} \cdots \tau_{l_1}^{\alpha_m} \cdots S_{i_k}^{\alpha_m} \tau_{1_1}^{\alpha_m} \cdots \tau_{l_1}^{\alpha_m},
\end{equation}

where \( \langle \alpha_1, \ldots, \alpha_m \rangle = \left\{ \alpha_1, \ldots, \alpha_m : \alpha_1 < \cdots < \alpha_m \right\} \).

The product in the multi-indices \( \langle i\ell \rangle \) can be computed by observing that the following relation holds in the thermodynamic limit:

\begin{equation}
\prod_{\langle i\ell \rangle} (1 + \psi_{(i\ell)}) = \sum_{m=0}^{\text{max}} \sum_{\langle \ell_{(i\ell)} \rangle} \psi_{(i\ell)} \cdots \psi_{(i\ell)} \text{,} \end{equation}

with \( m_{\text{max}} \sim (NK^M) / K! L! \).

We find Eq.(173) by putting Eqs.(15) and (14) into (12) and using the following identities to introduce auxiliary variables:

\begin{equation}
\int dq_{\alpha_1 \cdots \alpha_m} \delta \left[ q_{\alpha_1 \cdots \alpha_m} - \frac{1}{N} \sum_{j=1}^{N} Z_{j} S_{j}^{\alpha_1} \cdots S_{j}^{\alpha_m} \right] = 1
\end{equation}

\begin{equation}
\int dr_{\alpha_1 \cdots \alpha_m} \delta \left[ r_{\alpha_1 \cdots \alpha_m} - \frac{1}{M} \sum_{l=1}^{M} Y_{l}^{\alpha_1} \cdots Y_{l}^{\alpha_m} \right] = 1
\end{equation}
Appendix C.3. Replica symmetric free-energy

We first compute the normalisation $\mathcal{N}$ for a given:

$$
\mathcal{N} = \int \left( \frac{d\bar{q}_0 d\hat{q}_0}{2\pi i} \right) \int \left( \frac{dr_0 d\hat{r}_0}{2\pi i} \right) \times \exp \left[ M^L N^K \frac{1}{K!} \mathcal{J}_q \bar{q}_0^K r_0^L - Nq_0 \hat{q}_0 - M r_0 \hat{r}_0 \right] \\
\times \prod_{j=1}^{N} \int \frac{dZ_j}{2\pi i} \exp \left[ Z_j \bar{q}_0 \right] \prod_{l=1}^{M} \int \frac{dY_l}{2\pi i} \exp \left[ Y_l \hat{r}_0 \right] \right] \\
\times \prod_{j=1}^{N} \frac{dZ_j}{2\pi i} \exp \left[ Z_j \bar{q}_0 \right] \prod_{l=1}^{M} \frac{dY_l}{2\pi i} \exp \left[ Y_l \hat{r}_0 \right].
$$

(C.17)

By using Cauchy’s integrals to integrate in $Z_j$ and $Y_l$ and Laplace’s method we get:

$$
\mathcal{N} = \exp \left\{ \text{Extr}_{\bar{q}_0, r_0, \hat{q}_0} \left[ \frac{M^L N^K}{K!} \mathcal{J}_q \bar{q}_0^K r_0^L - Nq_0 \hat{q}_0 - M r_0 \hat{r}_0 \right] \\
+ \sum_{j=1}^{N} \ln \left( \frac{\bar{q}_0}{C_j} \right) + \sum_{l=1}^{M} \ln \left( \frac{r_0}{L_l} \right) \right\}.
$$

(C.18)

The extremisation above yields the following equations:

$$
\bar{q}_0 = \frac{1}{N} \sum_{j=1}^{N} C_j = \bar{C} \quad (C.19)
$$

$$
r_0 = \frac{1}{M} \sum_{l=1}^{M} L_l = \bar{L} \quad (C.20)
$$

$$
q_0^K r_0^L = C \frac{(K-1)!L!}{NK-1-M}. \quad (C.21)
$$

The variables can be normalised as:

$$
\frac{q_{\alpha_1\cdots\alpha_m}}{q_0} \rightarrow q_{\alpha_1\cdots\alpha_m} \quad \frac{r_{\alpha_1\cdots\alpha_m}}{r_0} \rightarrow r_{\alpha_1\cdots\alpha_m}.
$$

(C.22)

By plugging Eqs. (C.18), (C.19), the above transformation into (173) and by using Laplace’s method we obtain:

$$
\langle Z^n \rangle_{A, \xi, \xi} = \text{Extr}_{q, r, \hat{q}, \hat{r}} \left\{ \exp \left[ \frac{\bar{C}}{K} \sum_{m=1}^{n} \sum_{\{\alpha_1\cdots\alpha_m\}} \mathcal{J}_m q_{\alpha_1\cdots\alpha_m}^K r_{\alpha_1\cdots\alpha_m}^L \right] \\
- \frac{N\bar{C}}{K} \sum_{m=1}^{n} \sum_{\{\alpha_1\cdots\alpha_m\}} q_{\alpha_1\cdots\alpha_m} \hat{q}_{\alpha_1\cdots\alpha_m} \\
- \frac{M\bar{L}}{K} \sum_{m=1}^{n} \sum_{\{\alpha_1\cdots\alpha_m\}} r_{\alpha_1\cdots\alpha_m} \hat{r}_{\alpha_1\cdots\alpha_m} \\
\times \prod_{j=1}^{N} \mathcal{P}_C(C_j) \prod_{l=1}^{M} \mathcal{P}_D(D_l) \\
\times \prod_{j=1}^{N} \left( \frac{C_j}{\bar{C}_j} \right) \text{Tr}(S^n) \left[ \langle \exp \left[ F_s \beta \xi \sum_{\alpha=1}^{n} S^\alpha \right] \rangle \xi \right]
\right\}.
$$
\[
\times \int \frac{dZ_j}{2\pi i} \exp \left[ \frac{Z_j \sum_{m=0}^{n} \sum_{\alpha_1 \cdots \alpha_m} \hat{q}_{\alpha_1 \cdots \alpha_m} S_{\alpha_1} \cdots S_{\alpha_m}}{Z_j^{\ell_j + 1}} \right] \\
\times \prod_{l=1}^{M} \left( \frac{D_l!}{\sqrt{\lambda_0}} \right) \mathcal{Tr}[\tau_l^\phi] \left[ \left\langle \exp \left[ F_{n,\beta} \sum_{\alpha=1}^{n} \tau_l^{\alpha} \right] \right\rangle \right] \\
\times \int \frac{dY_l}{2\pi i} \exp \left[ \frac{Y_l \sum_{m=0}^{n} \sum_{\alpha_1 \cdots \alpha_m} \hat{r}_{\alpha_1 \cdots \alpha_m} \tau_{\alpha_1} \cdots \tau_{\alpha_m}}{Y_l^{\ell_l + 1}} \right] \right) \right) \right) (C.23)
\]

where \( \mathcal{T}_m = e^{-n \beta \gamma} \cosh^n(\beta \gamma) \tanh^m(\beta \gamma) \).

We can rewrite the replicated partition function as:
\[
\langle Z^n \rangle_{A,\xi,\phi} = \exp \left\{ N \text{Extr}_{q_r,\hat{q},\hat{r}} \left[ \frac{C}{K} g_1 - C g_2 - \mathcal{T} g_3 + g_4 + g_5 \right] \right\} \tag{C.24}
\]

Introducing the replica symmetric ansatz:
\[
q_{\alpha_1 \cdots \alpha_m} = \int dx \pi(x) x^m \quad \hat{q}_{\alpha_1 \cdots \alpha_m} = \int d\hat{x} \hat{\pi} (\hat{x}) \hat{x}^m \tag{C.25}
\]
and
\[
r_{\alpha_1 \cdots \alpha_m} = \int dy \phi(y) y^m \quad \hat{r}_{\alpha_1 \cdots \alpha_m} = \int d\hat{y} \hat{\phi} (\hat{y}) \hat{y}^m. \tag{C.26}
\]

By introducing Nishimori’s condition \( \gamma \to \infty \) and \( \beta = 1 \), we can work each term on (C.24) out and find:
\[
\mathcal{G}_1(n) = \mathcal{T}_0 + \mathcal{T}_1 \sum_{\alpha} q_{\alpha}^{K,L} + \mathcal{T}_2 \sum_{(\alpha_1 \alpha_2)} q_{\alpha_1 \alpha_2}^{K,L} + \cdots \tag{C.27}
\]
\[
= \frac{\cosh^n(\beta \gamma)}{e^{n \gamma \beta}} \int \prod_{j=1}^{K} dx_j \prod_{l=1}^{L} dy_l \phi(y_l) \\
\times \left[ 1 + \frac{n!}{(n-1)!} \tanh(\beta \gamma) \prod_{j=1}^{K} x_j \prod_{l=1}^{L} y_l \right] \\
+ \frac{n!}{(n-2)!} \tanh^2(\beta \gamma) \prod_{j=1}^{K} x_j^2 \prod_{l=1}^{L} y_l^2 + \cdots \\
= \frac{\cosh^n(\beta \gamma)}{e^{n \gamma \beta}} \int \prod_{j=1}^{K} dx_j \pi(x_j) \prod_{l=1}^{L} dy_l \phi(y_l) \\
\times \left[ 1 + \tanh(\beta \gamma) \prod_{j=1}^{K} x_j \prod_{l=1}^{L} y_l \right]^n \\
\xrightarrow{\gamma \to \infty} \frac{1}{2^n} \int \prod_{j=1}^{K} dx_j \pi(x_j) \prod_{l=1}^{L} dy_l \phi(y_l) \left[ 1 + \prod_{j=1}^{K} x_j \prod_{l=1}^{L} y_l \right]^n,
\]
\[ \mathcal{G}_2(n) = 1 + \sum_{\alpha} q_\alpha \hat{q}_\alpha + \sum_{(\alpha_1 \alpha_2)} q_{\alpha_1 \alpha_2} \hat{q}_{\alpha_1 \alpha_2} + \cdots \\
= \int dx d\hat{x} \, \pi(x) \hat{\pi}(\hat{x}) \left[ 1 + x \hat{x} \right]^n. \tag{C.28} \]

Similarly,

\[ \mathcal{G}_3(n) = 1 + \sum_{\alpha} r_\alpha \hat{r}_\alpha + \sum_{(\alpha_1 \alpha_2)} r_{\alpha_1 \alpha_2} \hat{r}_{\alpha_1 \alpha_2} + \cdots \\
= \int d\eta d\hat{\eta} \, \phi(\eta) \hat{\phi}(\hat{\eta}) \left[ 1 + \eta \hat{\eta} \right]^n. \tag{C.29} \]

\[ \mathcal{G}_4(n) = \frac{1}{N} \sum_{j=1}^{N} \ln \left( \sum_{C_j} \mathcal{P}_C(C_j) \left( \frac{C_j!}{q_{C_j}^{N}} \right) \right) \\
\times \text{Tr}_{\{S^+\}} \left[ \left\langle \exp \left[ F_\beta \xi \sum_{\alpha=1}^{n} S_j^\alpha \right] \right\rangle_\xi \right. \\
\times \frac{1}{2 \pi i} \oint dZ_j \exp \left[ \frac{Z_j \sum_{m=0}^{n} \sum_{(\alpha_1 \cdots \alpha_m)} \hat{q}_{\alpha_1 \cdots \alpha_m} S_j^{\alpha_1} \cdots S_j^{\alpha_m}}{Z_j^{C_j+1}} \right] \right] \tag{C.30} \]

\[ = \frac{1}{N} \sum_{j=1}^{N} \ln \left( \sum_{C_j} \mathcal{P}_C(C_j) \left( \frac{C_j!}{q_{C_j}^{N}} \right) \right) \\
\times \text{Tr}_{\{S^+\}} \left[ \left\langle \exp \left[ F_\beta \xi \sum_{\alpha=1}^{n} S_j^\alpha \right] \right\rangle_\xi \right. \\
\times \frac{1}{2 \pi i} \oint dZ_j \exp \left[ \frac{Z_j \int d\hat{x} \hat{\pi}(\hat{x}) \prod_{\alpha=1}^{n} (1 + S_j^\alpha \hat{x})}{Z_j^{C_j+1}} \right] \right] \\
= \ln \left( \sum_{C_j} \mathcal{P}_C(C_j) \right) \int_{C_j} \prod_{l=1}^{C_j} d\hat{x}_l \, \hat{\pi}(\hat{x}_l) \left[ \sum_{S=\pm 1} \langle e^{-F_\beta \xi S} \rangle_\xi \prod_{i=1}^{C_j} (1 + S \hat{x}_i) \right]^n \]

In the same way:

\[ \mathcal{G}_5(n) = \frac{1}{M} \sum_{l=1}^{M} \ln \left( \sum_{D_l} \mathcal{P}_D(D_l) \left( \frac{D_l!}{r_{D_l}^{N}} \right) \right) \tag{C.31} \]

\[ \times \text{Tr}_{\{\tau^+\}} \left[ \left\langle \exp \left[ F_\tau \zeta \sum_{\alpha=1}^{n} \tau_l^\alpha \right] \right\rangle_\zeta \right. \\
\times \frac{1}{2 \pi i} \oint d\gamma \exp \left[ \frac{\gamma \sum_{m=0}^{n} \sum_{(\alpha_1 \cdots \alpha_m)} \hat{r}_{\alpha_1 \cdots \alpha_m} \tau_l^{\alpha_1} \cdots \tau_l^{\alpha_m}}{\gamma^{D_l+1}} \right] \right] \]
\[
\begin{align*}
&= \frac{1}{M} \sum_{l=1}^{M} \ln \sum_{D_l} \mathcal{P}_D(D_l) \left( \frac{D_l!}{\tau_0^{D_l}} \right) \\
&\times \text{Tr}_{\{D_l\}} \left[ \left\langle \exp \left[ F_n \beta \zeta \sum_{a=1}^{n} \tau_a^a \right] \right\rangle_{\zeta} \right] \\
&\times \oint \frac{dY_i}{2\pi i} \exp \left[ Y_i \int d\hat{\chi} \hat{\phi}(\tilde{\gamma}) \prod_{a=1}^{n} (1 + \tau_a \tilde{\gamma}) \right] \\
&= \ln \sum_{D_l} \mathcal{P}_C(D_l) \int \prod_{l=1}^{D_l} d\hat{\chi} \hat{\phi}(\tilde{\gamma}) \left[ \sum_{\tau = \pm 1} \langle e^{F_n \beta \zeta \tau} \rangle_{\zeta} \prod_{l=1}^{D_l} (1 + \tau \tilde{\gamma}) \right]^n
\end{align*}
\]

By using Eq.(166) we can write
\[
f = - \frac{1}{\beta} \text{Extr}_{\pi, \tilde{\chi}, \phi, \tilde{\phi}} \frac{\partial}{\partial n} \left. \left[ \frac{C}{K} \mathcal{G}_1(n) - \frac{C}{K} \mathcal{G}_2(n) - \mathcal{T} \mathcal{G}_5(n) \right] \right|_{n=0} \quad \text{(C.32)}
\]
what yields free-energy (176).

**Appendix C.4. Viana-Bray model: Poisson constructions**

The Viana-Bray (VB) model is a multi-spin system with random couplings and strong dilution [VB85]. We can introduce a VB version of our statistical mechanical formulation for MN codes. The Hamiltonian for a VB-like code is identical to Eq.(160):
\[
\mathcal{H}_{\mathrm{gauge}}(\mathcal{S}, \tau; \xi, \zeta) = -\gamma \sum_{\langle j, l \rangle} \mathcal{A}_{j, l} (S_{j_1} \cdots S_{j_k} \tau_{l_1} \cdots \tau_{l_l} - 1) \\
- F_s \sum_{j=1}^{N} \xi_j S_j - F_n \sum_{l=1}^{M} \zeta \tau_l.
\]  

The variables \( \mathcal{A}_{j, l} \) are independently drawn from the distribution:
\[
P(A) = \left( \frac{L!K!}{M^{L+1}N^K} \right) \delta(A) + \frac{L!K!}{M^{L+1}N^K} \delta(A - 1).
\]  

The above distribution will yield the following averages:
\[
\left\langle \sum_{\langle j, l \rangle} \mathcal{A}_{j, l} \right\rangle_{A} = M \quad \text{(C.35)}
\]
\[
\left\langle \sum_{\langle j_1 = \cdots = j_k \rangle} \mathcal{A}_{j, l} \right\rangle_{A} = C \quad \text{(C.36)}
\]
\[
\left\langle \sum_{\langle j_1 = \cdots = j_k \rangle} \mathcal{A}_{j, l} \right\rangle_{A} = L. \quad \text{(C.37)}
\]
In the thermodynamic limit the above summations are random variables with a Poisson distributions:

\[
P \left\{ \sum_{(jl)} A_{jl} = x \right\} = e^{-M} \frac{M^x}{x!}
\]

\[
P \left\{ \sum_{(j_{1} = j \cdots j_{k_{1} = 1 - L})} A_{jl} = x \right\} = e^{-C} \frac{C^x}{x!}
\]

\[
P \left\{ \sum_{(j_{1} \cdots j_{k_{1} = L - L})} A_{jl} = x \right\} = e^{-L} \frac{L^x}{x!}
\]

Since the variance of a Poisson distribution is given by the square root of the mean in the thermodynamic limit:

\[
P \left\{ \sum_{(jl)} A_{jl} = x \right\} \xrightarrow{M \to \infty} \delta (x - M).
\]

The Poisson distribution for the construction variables \( C \) and \( L \) will imply that a fraction \( N e^{-\overline{T}} \) of the signal bits and \( M e^{-\overline{T}} \) of the noise bits will be decoupled from the system. These unchecked bits have to be estimate by randomly sampling the prior probability \( P(S_j) \), implying that the overlap \( \rho \) is upper bounded by:

\[
\rho \leq \frac{1}{N} \left[ N - N e^{-\overline{T}} + N e^{-\overline{T}} (1 - 2 p_e) \right]
\]

\[
\leq 1 - e^{-\overline{T}} + e^{-\overline{T}} (1 - 2 p_e)
\]

\[
\leq 1 - 2 p_e e^{-\overline{T}}.
\]

Therefore, a VB-like code has necessarily an error-floor that decays exponentially with the \( \overline{T} \) chosen.
